Stellar motions exhibit a number of cases in which stars apparently wide apart in the sky share a common motion. When this can be established, the distances of the stars concerned can be found, even if the stars are too far away for a reliable determination of trigonometric parallax. Some important cases occur, as has been shown recently by Dr. Eggen, of the Royal Greenwich Observatory. A further case of stellar motion is that of the Cepheid variables. These are all too far away to show measurable trigonometric parallaxes, but the average motion relative to the Sun and its dispersion can be found from radial velocities alone. The distances can be found from the period–luminosity relation, apart from a constant multiplier. This constant multiplier can be chosen to make the average proper motion agree with the average radial velocity. The result is a determination of the zero point of the period–luminosity relation among Cepheid variables. This determines the distance of the Large Magellanic Cloud and indeed of all objects including extra galactic nebulæ which contain Cepheid variables.

CHEMISTRY IS NOT ENOUGH

DR. JAMES TAYLOR reminds us in his presidential address to Section B (Chemistry) that for better or for worse we are living in a society which is based physically on Western science and technology. This has inescapable consequences for the scientist.

To the everyday world science is only a means to an end and not an end to itself. Science is not enough. Chemistry is not enough. Modern societies are pre-occupied with efforts to improve their material conditions. The means which are used depend on the application of scientific knowledge. Only scientists have the necessary training for establishing and using the technologies required to exploit recent major discoveries and those likely to arise in the future. It is clear that they will be brought more and more into technology, and thus into industry, the vehicle by which mankind exploits science for his own ends. It is certain that Huxley's view "that the chief aim of the scientist should be to increase material knowledge rather than human convenience" cannot prevail in modern society, which will be forced to deploy its scientists in a manner conducive to fulfilling its objectives.

The scientist must come down from his ivory tower and play a full part in developing the 'good life'; not merely as a narrow specialist supplying the data of invention, but also in the whole complex of problems which confront us. To prosper we must have an adequate supply of new discoveries and ideas to provide for future progress. In the future such discoveries are only likely to come from the professionally trained scientist and, particularly, the 'academically trained' individual. The laboratory discovery, however, is only one event in a long train which culminates in successful manufacture, and the follow-up involves applied research, development and chemical engineering, in all of which the chemist plays an important and growing part.

While formerly chemical industry was directed by men of non-scientific education, nowadays their place has largely been taken by men with scientific education. Equally important, such men have achieved, in considerable numbers, general and administrative responsibility in financial, commercial, sales and personnel positions throughout the chemical industry, and thus for the first time the scientist is in the position to fashion the ends as well as the means. Scientists are also making an increasing contribution in work study, operational research, analysis of requirements and the study of overheads. In its widest sense the scientists' contribution to industry can be regarded as a philosophy of approach: it is the application of a particular mental attitude which can be shared alike by the scientist, the financier, the salesman and, in the final analysis, the workman.

The scientist and chemist makes his initial contribution via pure science then via technology and industry. He has accepted technology and industry, but finally in the wider world of politics and affairs, where as yet he has neither been accepted nor indeed applied himself, he must deliberately reach out and become an active force. This is his destiny; to this end he was born.

PLEISTOCENE HISTORY OF THE IRISH SEA

TO-DAY—as in earlier interglacial periods—the Irish Sea forms a water-barrier separating Ireland from Britain. But during the Pleistocene glaciations its basin was a broad dry valley down the floor of which ice from Scotland advanced southwards. It was with this in mind that Mr. G. F. Mitchell (Trinity College, Dublin) opened his presidential address to Section C (Geology).

During a later phase of the last (Weichsel) glaciation, ice pressed up against the mountains of Wicklow and of Wales, and the corresponding deposits can be readily recognized on both sides of the Irish Sea. At the same time a lobe of ice advanced down the Cheshire Plain, discharging its melt-waters into the Severn valley; layers of mud in the melt-water gravels have a radiocarbon age of 42,000 years. At Chelford a deposit of mud, which lies below the deposits of this ice-lobe and contains wood of spruce, pine and birch, has a radiocarbon age of 57,000 years. This mud should thus belong to an interstadial stage within the last glaciation. Nothing is known of the early stages of the Weichsel glaciation in the Irish Sea basin.

A freshwater deposit at Ardcavan in Wexford is assigned to the last (Eem) interglacial period. It indicates temperate conditions and a sea-level no higher than that of to-day. In England also the deposits of corresponding age at Cambridge, Ipswich, London and Selsey all lie close to modern sea-level, and give no positive evidence of a high sea-level around the British Isles during this interglacial period.

During the preceding (Saale) glaciation ice advanced as far as Hoxne in East Anglia, where it deposited Gipping boulder clay on top of the famous interglacial deposit. There was a corresponding advance down the Irish Sea, from the floor of which the ice incorporated marine clays and shells. A calcareous shelly boulder clay (easily recognized in many localities) can be traced as far as Cork in Ireland and Fremington in Devon. This advance was preceded and succeeded by local phases in which ice from the mountains of Ireland and of Wales descended into the Irish Sea valley.

The preceding (Holstein) interglacial period saw the Irish Sea standing perhaps 100 ft. above its present level, and its shores covered by evergreen forest. At Kilbeg, Waterford, trees such as fir, spruce, pine, yew, rhododendron and box were dominant, and the deciduous trees were poorly represented. In Barnstaple Bay the beach deposits below the Fremington boulder clay rise to 60 ft. above present sea-level, while still greater heights are recorded in eastern England at Kirmington and the Nar valley.

In the Weichsel and the Saale glaciations ice advanced far south in eastern England and in the Irish Sea. In the Elster glaciation ice reached the Thames valley, and there must have been a corresponding advance in the west. The younger (Holstein) beach of the Irish Sea contains far-travelled erratics, the transport of which is usually attributed to floating ice. But the glacial seas had their shores far to the south and at much lower levels, and only an ice-sheet of Elster age could have carried these erratics to the levels at which they are now found around the Irish Sea. The Giant's Rock near Porthleven in Cornwall and the erratics of the Cork coast indicate the limits of advance.

For the preceding (Cromer) interglacial period we have no record of the vegetation. But a widely distributed shore-platform shows that the Irish Sea must have stood for a considerable time about 20 ft. above its present level. The beds at St. Erth and the Red Crag shells in secondary position in the Isle of Man and in Wicklow show that there must have been still earlier marine periods in the basin.

When the ice of the last glaciation retreated up the Irish Sea it deposited three large moraines. The first runs from Wexford to the Lleyn Peninsula about 320 ft. below modern sea-level, the second from Wicklow to the same point 270 ft. down, and the third from north Dublin to the Isle of Man and thence to England at the same depth. The first moraine may have been quickly drowned by the rising waters of the postglacial sea, but the second and third probably persisted for some time, and provided routes for the postglacial migration of plants and animals into Ireland. If the link between Ireland and the Isle of Man was severed before—but only a short time before—the link between the Isle of Man and Britain, then many of the puzzling features of the modern flora and fauna of the Isle of Man find ready explanation.

TROPICAL CLIMATES AND BIOLOGY

In his presidential address to Section D (Zoology), Dr. G. S. Carter took as his subject a comparison between the results of tropical and temperate biology, emphasizing especially work in the tropics which has given results not to be expected from our knowledge of temperate biology. As an introduction to his address, he gave a short account of the climatic conditions in the tropics that seem most likely to be biologically important, especially the less-marked seasonal rhythms of tropical climates, and the greater importance of variations in the amount and type of the rainfall in determining the nature of environments.

His first example of biological work in the tropics that has given results unlike those of similar work in temperate regions was investigation of the conditions of life in shallow and stagnant tropical swamps. The waters of such swamps are always markedly and sometimes almost completely de-oxygenated, even close to the surface. This is due to several conditions resulting from the tropical climate and not present in similar temperate waters. Of these conditions the most important are protection from wind disturbance by thick plant growth above the water, absence of overturn in the warm tropical nights, and rapid absorption of any oxygen that reaches the water in the chemical and biological processes of decay at the high temperatures. The faunas of tropical swamps are variously adapted to these conditions. The swamps are the habitat of most of the known air-breathing species of fishes, and the invertebrates show many different kinds of adaptation to life in a de-oxygenated environment.

The distribution of sulphur compounds in African lakes gives a second example of unexpected results in tropical biology. In Lake Victoria and other lakes the sulphur content of the water is very low. But when the mud at the bottom of the lake is examined, it is found that its content of sulphur is extremely high to depths of at least 10–15 m., and, surprisingly, that the sulphur in the mud is almost all in organic compounds. It seems that the fauna absorbs sulphur compounds from the water, which thus becomes denuded of sulphur; the sulphur in their bodies is carried down to the mud when they die; and—this is the surprising feature—the sulphur compounds so brought into the mud do not break down even in the thousands of years needed for the deposition of 10 m. of mud. Sulphur can be returned from the mud to the water only if it is absorbed by the roots of the aquatic plants, which contain a normal concentration of sulphur. No similar situation is known in temperate waters.

The control of seasonal rhythms of breeding and migration in the many tropical environments that are nearly invariable in climate throughout the year is a problem not met with in temperate biology. In equatorial rain-forests the only significant seasonal climatic change is in rainfall, and even in rainfall the variation is more in amount than in frequency, for rain falls at intervals of not more than a few days at any time of the year. Yet even in these environments most species show seasonal periodicity of breeding, and many migrate to other regions at definite times of the year. How these periodicities are controlled and especially whether endogenous rhythms play any part in their control was considered.

Finally, the means by which small mammals are able to maintain their water-balance in desert environments was discussed, and, in conclusion, a plea was made for more work in the wide and still largely unexplored field of tropical biology.

WELSH EMIGRATION OVERSEAS

Prof. E. G. Bowen, being head of the Department of Geography and Anthropology at the University College of Wales, Aberystwyth, could scarcely have chosen a more apt subject for his presidential address to Section E (Geography) than "Welsh Emigration Overseas". As he points out, Wales has made a very substantial contribution for its size to the peopling of new territories overseas.

In the main, Welsh emigrants have left their homes seeking employment similar to that which they were accustomed to in Wales. They became farmers, miners, quarry workers and tinplate workers in the New World and in Africa; while in earlier times others had left the homeland in search of religious or political freedom. At present, the majority of Welsh people overseas are engaged in commercial, administrative or educational work. In recent years, the historians have gathered together a considerable amount of information regarding Welsh emigration to individual countries, but no one has yet attempted an overall picture, or examined the matter from a strictly geographical point of view. All this has been made possible by plotting the data assembled at Dolgellau by the Society of Welsh People in Dispersion (Undeb y Cymry ar Wasgar). The overall picture brings out most of the points mentioned above.

Special attention has been directed to the Welsh communities in those countries, such as the United States of America and the Argentine, which lie outside the British Commonwealth. The famous Welsh Colony on the banks of the Chubut River in Patagonia is studied in some detail, and much new evidence is made available concerning the preparations made for the great adventure in the middle of the past century, and the extent to which the Welsh emigrants were misled before they left their native land, concerning the geographical conditions they were going to find in their new homeland in the South Atlantic.

MONETARY THOUGHT AND MONETARY POLICY IN ENGLAND

THE purpose of Prof. R. S. Sayers's presidential address to Section F (Economics) is to review the theoretical approach to the problems of monetary policy, in the light of changes in the institutional and political environment. It is confined to questions of internal policy: the theory is that of a closed system.

Since 1800 all policy has been based on a broad quantity theory approach: a simple supply-and-demand analysis, in which money is regarded as basically different from other commodities. Although the abstract sense of money, as the unit of account, is unambiguous, money in the concrete sense—the medium of exchange—has no parallel sharpness. It is impossible to identify money either by reference to use, or by the absence of interest, and the distinction between active money and idle money is only notional and may mislead.

For the purposes of policy we have to think of the pressure of total demand, and for this purpose all claims potentially useful for incurring market commitments are relevant. This includes the gross volume of trade credit, variations in which can dwarf variations in bank credit. Non-bank credit has no regular proportionality to bank credit. If all these problems are re-formulated with the use of the conventional concept of velocity of circulation, the conclusion remains the same, and there remains the question whether any disturbance sets up equilibrating forces.

The question of the relation between an acknowledged kind of money and other assets with some monetary quality has been debated continually since 1800, sometimes (as in the 'Currency School' period) with great vigour; these controversies are reviewed in some detail. It is argued that the equilibrating mechanism depended on the power of bank rate to instil fears of trade depression, that during a long period this mechanism was overlaid by the extraordinary power of bank rate over the foreign exchange situation, and that the power has been undermined by the 'full employment' policy.

In the inter-war period more attention was given to the equilibrating mechanism, and ideas about the function of the rate of interest in this mechanism were developed particularly by Keynes. These developments in monetary thought are briefly reviewed, and it is shown that the formulations then used continued to depend on the notion that the supply of the means of final payment was of critical importance. The dangers of this kind of analysis have since been underlined by the development of financial intermediaries and by the behaviour of trade credit. In a rising boom, the sources of liquidity broaden, and the rising demand for the means of payment comes too late and is too easily satisfied.

These developments have tended to make the banks relatively less influential, and to narrow the basis on which direct authoritative action has traditionally been imposed. This negative conclusion is the most important of the examples given to show how the shape of theoretical analysis bears upon the practical problems of policy.

STATICS AND THE ENGINEER

SIR ALFRED PUGSLEY'S presidential address to Section G (Engineering), which is prefaced by an indication of the notional difficulties that arise in statics when divorced from engineering and is closed by an emphasis on the power and grace of statics, touches on the interests of schoolboys, mathematicians and engineers alike.

An introductory section brings out the way in which mathematics, and particularly statics, entered into constructional engineering, and seeks to show how the relation between theory and practice in engineering has changed from one in which mathematicians were imposed on engineers to one in which, at least in statics, engineers themselves embrace the theory and seek to advance it.

The outcome of this change is then illustrated in some detail by reference to developments in applied statics in a number of fields. The new understanding of solid friction is seen as the result of a replacement of the smooth rigid body notions of classical mechanics by the realistic, rough and deformable-body ideas of the engineering subject of strength of materials. The limitations of nineteenth-century methods of analysing frameworks, based upon classical statics, are seen to fade before the more general energy methods of this century, linked with ideas of elastic strain-energy; and these energy methods are themselves seen to develop—albeit hesitantly—in the hands of engineers. Some attention is also given to the efforts of engineers to achieve economy in the arrangement of their frameworks.

It is an easy transition from the problems of the plane and space frames of great bridges and airships to those of modern suspension bridges. Here there is added to the usual linear problems of strain energy a non-linear gravitational energy problem due to the great weight of the bridge itself compared with the applied loads arising from crossing traffic.

The development of statics for and by engineering works is further illustrated by the problems that arise in the thin tubular structures of ballistic missiles, the reinforced shells of submarines, and the bathyscaphe cabins of Piccard and his successors for deep-sea exploration. The static stability problems of such tubular and shell-like structures are briefly examined and seen to present new challenges for the future.

THE PEASANT AND THE PAST

PROF. ESTYN EVANS, in his address to Section H (Anthropology), spoke of the peasant and the past, and the significance of present-day folk-life studies for the interpretation of archæological evidence and the better understanding of the food-producing societies of Neolithic and later times. An intense interest in the whole past of man on Earth was a feature of the present age, stimulated on one hand by a growing sense of world unity, and on the other by discoveries which had brought the means of giving precision to the chronology of human history in periods before written records were kept. Some peasant values appeared to be so universal and resistant to change that they may help to illuminate the past. The term peasantry, stripped of its sentimental associations and derogatory implications, could be defined as a traditional society for whom farming was a way of life and not a business investment. It was a part-society standing in a two-way relationship with an élite which was normally an urban society. It had to be sufficiently stable and technologically advanced to be worth exploiting in one way or another, and possession of the plough and traction animals, with distinctive regional types of settlements and field-systems, were normal concomitant features. These indices were traceable by archæological methods, and it could be shown that peasantries or near-peasantries were of long standing in many parts of the Old World. Interpretation of the material evidences of archæology could be supplemented by the use of parallels drawn from folk-life studies among surviving peasantries.

Ecological studies of peasant societies were badly needed. Social anthropologists had tended to devote their attention to 'primitives' and they were often so pre-occupied with such matters as kinship that they paid inadequate attention to variations in economy, technology and society in relation to environment. It was dangerously easy to find isolated analogies between societies far removed in space, and it was more profitable to investigate regional examples before trying to establish universals. In an attempt to trace continuities by using evidence drawn from folk-life studies and archæology, Prof. Evans took Ireland as his example, a region where the archæological record was relatively short and complete, where a vast amount of oral tradition was available, and where peasant folk-ways had not entirely succumbed to the accelerated forces of change. It was sometimes objected that such local studies, by seeking continuities, could lead to the false conclusion that civilization was indigenous. They might, at the worst, breed parochialism and a narrow nationalism. "In groping backwards through our own past," said Dr. Evans, "it is important that we should not ignore the warning light brandished, however provocatively, by the diffusionists, and so fall into the trap of regarding civilization as the product of local evolution."

In fact, folk-lore tended to focus its attention on the periods and phenomena of contact and could thus provide a guide to acculturation. At such critical periods folk-lore and folk-ways tended to be revitalized, though they usually changed their forms in the process. Or outmoded ways, driven underground, assumed magic powers, and many curious survivals provided clues to practices that were probably once widespread. The establishment of more folk-museums as instruments of record and research was urgently called for.

Prof. Evans concluded by directing attention to the relevance of such research to the theme of the Cardiff symposium on world food supplies and population. Perhaps two-thirds of the world's population were primary food-producers at, or not far removed from, peasant-levels. Their practices and values were often out of step with the modern world, but in many areas improved standards of living could be obtained with least disruption by respecting the institutional framework of peasant societies. We should know more about them before they are finally transformed and lose their links with the past.

PHYSIOLOGY OF HEARING

In recent years considerable advances have been made in auditory physiology, especially that of the internal ear. At present, also, there is increased interest in noise as an environmental factor, stimulated largely by the introduction of turbo-jet aircraft into commercial operations, and questions are frequently raised on the possible effects of noise on health, working efficiency and hearing. The time was thus opportune for Prof. W. Burns to choose "The Physiology of Hearing" as the subject of his presidential address to Section I (Physiology and Biochemistry).

Considering first the physiology of the peripheral mechanism, the chief interest resides in the mechanism whereby the ear attains its astonishing degree of sensitivity, such a large dynamic range, and how it can act as a peripheral resolving mechanism for different levels of sound intensity and for different frequencies of sound. The original brilliant theorizations of Helmholtz, and the contributions of Rutherford and others, have now been put to the test of rigorous experimental investigation, using refinements of technique and new approaches, especially those made possible by electronic means. The mechanism of the middle ear and the movements of the structures of the cochlea of the internal ear, as a result of sound stimuli, have been established beyond doubt by the series of brilliant investigations, carried out over a period of years, by G. von Békésy. He has shown by direct microscopic inspection by normal and stroboscopic illumination that the movement of the basilar membrane and associated structures, collectively known as the cochlear partition, essentially takes the form of travelling waves of transverse displacement. These originate at the base of the cochlea and travel towards the apex, in response to sound stimuli. These waves of displacement increase in amplitude, reach a maximum, and then rather rapidly die away. The position of maximum amplitude is broadly determined by the frequency of the causal sound, the high frequencies near the base, and lower frequencies near the apex. The lowest frequencies involve the whole cochlea.

These findings, although they do not substantiate any of the earlier theories, do imply a form of resonance, albeit a rather broad and unselective one, which is capable of performing a somewhat low-grade form of frequency analysis at the periphery.

The means whereby this resonance pattern is transformed into nerve impulses has been intensively investigated, especially at the Central Institute for the Deaf at St. Louis by Hallowell Davis and his collaborators. In a long series of investigations, the findings of Békésy on the vibrational patterns of the cochlea have been confirmed by electrical means and much new information of outstanding importance has been obtained. It now appears that the electrical positivity of the scala media with respect to other tissues is maintained by metabolic activity of the groups of cells known as the stria vascularis, and that this potential represents a store of energy which can be released for the purpose of stimulating the auditory nerve endings when the organ of Corti is moved by sound vibrations. The potential changes known as the cochlear microphonic and its associated potentials, called by Davis summating potentials, now appear to be derived from movements in various directions of the hair cells by displacement of the hairs. These displacements are caused by relative movement between the upper surface of the organ of Corti and the overlying tectorial membrane, in which the hairs are embedded. The anatomically distinct group of hair cells, known as the external hair cells, appear to have a separate function and lower thresholds compared with the external group of hair cells. The cochlear microphonic potentials seem to originate solely from the external hair cells; these potentials are an electrical transcript within limits of the sound stimulus, and together with the summating potentials which, in part, originate from the internal hair cells, appear to act as the stimulus for the action potentials of the auditory nerve. It is now becoming clearer how the information on intensity and frequency of sound is coded in the auditory nerve and that further resolution is added by the activity of synaptic mechanisms higher up the afferent pathways to the brain centres.

In considering the effects of noise on hearing, as distinct from its effects of working efficiency or peace of mind, difficulties arise because of the complexity and variety of different noises, and the variability in susceptibility to hearing damage in different people. However, three types of effect of noise on hearing can be distinguished. Noise may produce temporary threshold shift, which is a reduction in sensitivity lasting for months, hours or days, as a result of exposure to sound. The reduction in sensitivity affects frequencies, in general, higher than those which caused the temporary effects, and this is clearly demonstrable in the case of pure tones, although wide-band noise shows the same tendency. Most of the temporary threshold shift is acquired in the earlier hours of a day spent in noise. The second effect may be called 'acoustic trauma'; and it may arise from short exposure to very intense noise, to a sudden explosive sound. Various degrees of permanent hearing loss, accompanied by some temporary loss, result. The third type is occupational hearing loss, in which daily exposure to noise in the course of work may eventually, perhaps after many years, produce permanent losses of hearing of various degrees. In this case temporary threshold shifts will also occur, but when these have passed off, residual permanent losses can be found. Occupational hearing loss tends to occur at the higher frequencies, and may be detected by an audiometric examination long before it is subjectively noticeable, or any social disability has occurred. Neglect of such signs, or continued exposure, however, will result in a progressive involvement of the lower frequencies, including those used for speech recognition, and if this is so the person will become aware, as will his family, of difficulties in understanding normal conversation.

Loss of hearing due to occupation occurs only in certain noise conditions and in certain people. Significant loss is avoidable by the use of certain measures which are not difficult, but may be tedious and time consuming. These measures include the measurement of the noise exposure in terms of intensity, frequency and duration; and the measurement of hearing. The assessment of hearing loss due to noise must take into account various personal factors, including age, to allow for the normal deterioration of hearing with advancing years. The greatest need at present is for more research into the precise relations between the different characteristics of noise exposure and the effect on the ear. In the meantime, tentative relationships are used in deciding whether a given response to noise is, on average, harmful and whether noise reduction, hearing protection, or other means should be used. However, better knowledge in this field will enable more precise and efficient hearing conservation to be practised.

EXPERIMENT IN PSYCHOLOGY—A CENTENARY AND AN OUTLOOK

THE publication, in 1860, of Gustav Theodor Fechner's "Elemente der Psychophysik" is commonly taken to be the starting-point of experimental psychology. Prof. R. C. Oldfield, in his presidential address to Section J (Psychology), traces some features of the subsequent history of the subject and referred especially to inter-relation of theory and experiment.

Fechner, he said, was an outstanding innovator. He introduced the stimulus–response method, made physical measurements throw light on psychological problems and systematized statistical and experimental design. Psychophysics was one of the first branches of biology to make use of quantitative methods. It was Fechner's misfortune to initiate a period of controversy over the problem of measuring sensation. Hermann Ebbinghaus, in his work on memory, shares with Fechner the distinction of first revealing simple quantitative relationships among phenomena at the psychological level. In both cases the outcome of their work is independent of its particular *rationale*, and its interpretation is still a matter of active inquiry. Bartlett's studies of memory, on the other hand, illustrate the usefulness of experimental work not constrained by the more rigid canons of laboratory procedure, and emphasize both the advantages and the dangers of introducing *ad hoc* concepts. These dangers are more evident still in the activities of the *Gestalt* school, though their brilliant record of novel experiment, and the decisive overthrow of gratuitous preconceptions regarding perception which they brought about, gave tremendous fresh impetus in a wide field of research.

More important, probably, in the long run, were the developments which led to the establishment of physiological and comparative psychology on a scientific basis. Watsonian behaviourism itself had at least the merit of provoking controversies which, when they had subsided, allowed a fresh start on a simpler and more direct basis. But the vital step was taken when S. I. Franz, in 1902, combined the quantitative systematic methods for the study of animal behaviour devised by Lloyd Morgan and Thorndike with the cerebral ablation techniques developed by the experimental neurologists of the nineteenth century. Following the extended pioneer work of Lashley, these forms of experiment are now proving remarkably fruitful, not only in the field of cognitive, but also of appetitive and affective, functions. Progress in these directions can be gained without the need for elaborate theoretical constructs. The importance of the psychologist keeping closely in touch with anatomical and physiological factors, Prof. Oldfield suggests, does not primarily lie in the immediate hope of explanations of psychological functions in these terms, but in maintaining theoretical simplicity and in bringing to light fresh phenomena for fruitful study.

Systematic observation of, and simple experiment on, animals behaving in their natural habitat, so extensively developed by the 'ethological' school, has formed the natural and fruitful complement to laboratory studies. The theoretical formulations of this school have proved less rigid than they initially appeared to be, and much may be expected by cross-fertilization between laboratory, and field, observation.

The possibilities of experiment on human beings are, however, not being neglected, and Prof. Oldfield gives one example, from the field of speech and language, where a fresh theoretical approach and new technical resources have led to rapid progress, with extension into other topics such as attention, where a century ago effective quantitative experiment would scarcely have been thought possible.

In concluding, Prof. Oldfield makes a number of observations about the prospects of experimental psychology. The most important factors making for good progress in the immediate future he believes are avoidance of parochialism, full and free collaboration between psychologists and workers in other relevant fields, the attraction of more young people of first-class ability into the subject and the provision of the right atmosphere for them to learn in as undergraduates and as graduate research students. He thinks that the future of the subject will be that of a biological discipline, destined one day, perhaps, to be instrumental in extending the present range of fundamental biological conceptions. The next hundred years promise exciting developments. But, feeling that there is little present evidence of any real wish on the part of human beings to understand themselves, he is unwilling to predict what their impact on people generally may be.

ORIGIN OF ANGIOSPERMS

ATTENTION was directed by Prof. T. M. Harris, in his presidential address to Section K (Botany), to the fact that fossil botanists have had notable success in bringing ancient plants to light, when they happened to have good material to study. They have been much less successful when they have directed their research to answer a specific question. Their longest sustained effort has been to discover the early ancestors of the flowering plants (Angiosperms), and here they have failed almost completely. The main thing that can be claimed on the credit side from much devoted research is that the fossils which they hoped they would be able to establish as ancestral flowering plants have been proved to be so different that no one now so regards them. Instead, they are representatives of extinct and strangely organized plant families. Progress has been made, but not in the way intended.

Unequivocal knowledge of some early flowering plants would not only satisfy the fossil botanists' desires; it would also have a profound effect on the botany of living plants. In two plant groups, the ferns and the conifers, the right sort of information is at hand from fossils; instead of interminable discussion there is simple agreement on the numerous botanical problems where the fossils tell a clear story.

In fact, little more is known now about the fossil history of flowering plants than in 1860, but what was a doubtful boundary of knowledge then is now a clear boundary. It was then known that fossil flowering-plant organs, leaves, wood, fruits, seeds were common throughout the Tertiary period and as far back as the Cretaceous period, but they ceased rather after the Middle Cretaceous. Before that there were plenty of ferns, conifers and other plants, but very few that suggested a flowering plant. Those few which did suggest one were afterwards taken up enthusiastically for study and shown to be nothing of the sort. Each decade has provided one or two new candidates, and most have since been rejected as the result of much hard work.

Fifty or a hundred years ago it was suggested that the flowering plants evolved in remote and geologically unexplored regions, perhaps near the North Pole, or perhaps on an isolated island, like New Zealand. Then, in the Cretaceous, geographical changes allowed them to escape and to spread over the Earth's surface and presently to exterminate most of the previous flora. As more is learnt, this kind of explanation becomes less likely; there is evidence now, for example, that the flowering plants arose at about the same time and in much the same manner in New Zealand as in Britain. There is, indeed, a current idea that they dominated the land a little earlier in the tropics than in high latitudes; but it is not yet agreed where the Cretaceous poles and tropics lay. There is, too, a current theory that they evolved first in dry and upland regions, the fossils of which are seldom preserved. These theories are, in part, excuses for failure and what is needed more than excuses is a hypothesis which is a recipe, if not for success, at least for vigorous work. It seems, too, that the days of these theories may be numbered now that fossil-pollen is being so widely studied. Pollen blows far, and if the flowering plants were anywhere in force before the Cretaceous it should be possible to find their pollen. So far, what is known is that their kind of pollen appears and increases at the same time as the leaves, or only a little earlier. Before the Cretaceous, there are a few claims for flowering-plant pollen grains, but then there are a few debatable leaves and other organs.

A hypothesis that does make for progress is that the ancestors of the flowering plants were present in the regions that have been studied and that they have been collected, but they have been unrecognized because they are not like modern flowering plants and have been wrongly classified. Anyone looking at a fossil flora where everything is neatly classified might think this preposterous; but, in fact, nearly all fossil genera are based on a single kind of organ known in isolation. Its classification is not secure, but merely tenuous reasoning from very scanty evidence. The genera of the text-books are the minute percentage of fully known ones.

These early fossils should be studied, not as early angiosperms, for that is to invite disappointment, but for whatever can be learnt about them. The new facts will provide surprises; that is, sometimes things will be found so new as to be contrary to expectation. Prof. Harris pointed out that nothing is more contrary to his own expectations when he studies a little-known fossil of pre-Cretaceous age that it will prove to be a flowering plant, but since it is almost unknown almost anything may happen: therein lies hope.

THE DANGEROUS CONCEPT OF THE NATURAL FOREST

RELATIVE to agriculture, forestry is still a very young science. The bulk of the world's timber still comes from natural, rather than managed, forests. This being so, it is perhaps not surprising, as Mr. T. R. Peace points out in his presidential address to Section K* (Forestry), that foresters should tend to turn to the natural forest as an ideal toward which they ought to aspire. Many mistakes have been made in the creation of artificial forests, and a tendency has developed to attribute these to departures from natural forest conditions. No one would deny the desirability of more research on forest relationships, but there is no need to evaluate these relationships on the basis of their occurrence in the natural forest. The agriculturist no longer bases his practices primarily on the behaviour of wild plants, and it is certainly necessary to consider whether the forester should do so.

A managed forest, in so far as timber is being removed from it, is inevitably different from a truly natural forest. In fact, there are normally many other differences, especially if the forest is planted. The forester often uses trees which are exotic to the area in which he is working. He usually creates even-aged and often pure forests, whereas natural forests are nearly always uneven-aged and mixed. The forester can improve his forest sites by practices such as ploughing and manuring. He can also improve his crops by selection of species, provenances or individual trees of especially high quality.

Believers in the natural forest tend to decry the use of exotics; but exotics have been planted successfully in many countries, especially in Britain. In any event, the conception of exoticism is based on a misunderstanding of the bases of the natural distributions of plants.

While it is admitted that pure crops inevitably present certain enhanced disease risks, it is clear that they have certain sylvicultural advantages. It should not be assumed that their disadvantages, where these occur, cannot be overcome by appropriate techniques.

From a production point of view, uneven-aged stands have very definite disadvantages. If one does not accept the concept of the inherent desirability of the natural forest, it is hard to find any good reason for their retention.

Admittedly, the use of pure coniferous crops may possibly have undesirable effects on forest soils. It is, however, clearly necessary that this effect should be better understood and evaluated, before admixture of broad-leaved trees is generally advocated. In this connexion, it is considered that the influence of mycorrhiza has often been exaggerated.

The study of the biological relationships of the natural forest will provide valuable data towards our understanding of forest relationships in general. It is, however, highly undesirable that the conditions existing in the natural forest should automatically be regarded as ideal, and any departures from them as retrograde steps.

If we are to make that progress in the acquisition of knowledge, which is necessary for a proper understanding of forest processes, it is dangerous to limit ourselves at this stage by putting forward general principles, even if they appear to have a sound foundation. To burden ourselves with a concept so vague as the general desirability of the natural forest is doubly dangerous.

SIXTY YEARS OF PROGRESS IN ENGLISH EDUCATION

IN his presidential address to Section L (Education), Prof. H. C. Dent points out that in 1900 England was educationally a sadly under-developed country. But the first decade of the twentieth century was one of explosive reform in many directions. Responsibility for all public education was for the first time vested in a single central authority by the establishment of the Board of Education, which took over in 1900. The Education Act, 1902, transferred local responsibility for public education from *ad hoc* school boards and voluntary bodies to the county and county borough councils, and, by granting them powers to provide and aid education 'other than elementary', created a statutory system of secondary education. This system was expanded rapidly, and its social range greatly widened by the introduction of the 'free place' scheme in 1907. Meanwhile, between 1900 and 1909 the number of universities in England was doubled.

Local education authorities were in 1906 empowered to provide school meals for necessitous children, and in 1907 required to set up a School Medical Service—a reform which within a generation effected a revolutionary improvement in child health.

The First World War focused attention on the exploitation of young workers. Though the attempt, made by the Education Act, 1918, to establish post-school day-continuation schools proved abortive, this Act established fourteen as the school-leaving age without exemptions, thus abolishing the 'part-time' system; and by requiring local education authorities to provide advanced and practical courses for older children in public elementary schools, paved the way towards secondary education for all.

A decisive step was taken towards this by the first Hadow Report of the Consultative Committee of the Board of Education, "The Education of the Adolescent", published in 1926, which presented the concept of education as a continuous process conducted in successive stages, of which the first, up to the age of eleven plus, should be regarded as 'primary' education, and the second, available to all, but in different forms to match different abilities, as 'secondary' education. Uneven but unceasing advance towards this ideal was made up to 1939 by 'Hadow reorganization'—the provision of separate schools for primary and post-primary education within the public elementary system. Further reports by the Hadow Committee, published in 1931 and 1933, offered blueprints of curriculum and method for the junior and infant sections respectively of the primary school. These are the bases of contemporary practice.

The Second World War initiated another era of explosive reform. The Education Act, 1944, re-organized the statutory system of public education into progressive stages, and established the principle of secondary education for all. Concurrently, there began an expansion of university and other higher education which bids fair to be without precedent in our history.

We are still in the earlier stages of the present advance. Perhaps more remains to be achieved than has been so far, especially in the sphere of quality. But what has been done since the War should not be under-estimated; it is a very remarkable achievement. The next ten years are likely to prove absolutely crucial, for within them we must match our man-power with our ambitions—we have not yet successfully done so.

PASTORAL SYSTEMS IN RELATION TO WORLD FOOD SUPPLIES

DR. WILLIAM DAVIES, in his presidential address to Section M (Agriculture), directed attention to the fact that world pastoral systems can be classified into five groups: (1) very intensive (supporting 80 cattle units per 100 acres), being typical of the best in Great Britain or New Zealand; (2) intensive (40 cattle units per 100 acres), the average in Great Britain; (3) moderately intensive (20 cattle units per 100 acres), typified by marginal grasslands in Great Britain; (4) extensive (10 cattle units per 100 acres), typified by ranching in the United States; and (5) very extensive (3–5 cattle units per 100 acres), which is typical of the extensive cattle ranching in Africa, Australia and the Americas.

International production data, as published by the Food and Agriculture Organization, are used to estimate the present stock carried in the various pastoral regions of the world. These data are reduced to the basis of a standard cattle unit, the latter being based on data collated and published by the British Grassland Society (1955). In the figure for cattle units all classes of domesticated grass-eating animals are included, for example, cattle, buffalo, horses, camels, mules, asses, sheep and goats.

Two-thirds of the area under 'grassland' in the five continents is occupied by extensive pastoral systems, and these carry about one-third of the total of the world population of grass-eating animals as calculated to a standard basis of cattle units. At the present time grass-eating farm animals total nearly 900 million cattle units for the world as a whole. Half of these are found within the 'tropics' (here defined as 30° N.–30° S.). These produce one-third of world meat supplies, one-fifth of the milk and other dairy produce and a large portion of the hides, skins and animal tallow in world trade.

Each pastoral system is examined, first in the *status quo* and then in terms of potential as suggested by the findings of grass/animal research and experimentation within each zone concerned. Very large and economically important advances have already been made as regards the improvement of grassland and increased output of meat and milk within the intensive pastoral systems of Europe, America and Australasia. Much research activity is in progress which suggests that yet greater advances in output from grassland are easily possible in the not too distant future.

As regards the extensive pastoral systems, few or no detailed grassland researches have been made until recently when Australia and East Africa in particular have caused such work to be initiated, already with notable advances. On the basis of the findings of currently conducted research there is evidence which suggests that large increases in total output of animal products are possible both technically and on the basis of economic profitability. If this proves true, then very large aggregate additions can be made to the world supplies of meat and milk following sound measures of grassland improvement on the ranches of the world.

The need is for agronomic research into the grass/animal/soil complex and particularly in extensive pastoral zones. There exists a serious paucity of both research and advisory agronomists. Farmers as well as governments everywhere must be made cognizant of this position, for if the world is to be fed adequately, there must be an increase in numbers and in gross outputs of farm animals. The answer lies in the steady improvement of grassland, animal and also of soil in every continent. This requires well-planned research and advisory services which are the intimate concern of adequately trained grassland agronomists who can offer sound guidance, but who must have the full support of governments and of the agricultural industry everywhere.

POPULATION GROWTH, FERTILITY AND POPULATION POLICY

IN his presidential address to Section N (Sociology), Prof. D. V. Glass remarks that although we are concerned with the population problems of to-day and of the near future, discussion is so often linked with the name of Malthus that it is desirable to re-examine the context in which Malthus wrote, and to consider whether his recommendations have any relevance now.

Malthus was far from opposed to population increase as such. His concern was with the *rate* of increase, and his recommendations aimed at reducing that rate by delaying marriage. He was opposed to birth control, not only on moral grounds but also because he regarded the 'tendency' of population growth to press upon the means of subsistence as itself a stimulus to individual industry and to social and economic progress. Birth control, he believed, by enabling parents to decide upon the number of their children, would remove that stimulus.

Since Malthus wrote, the main elements in his argument have been largely discarded. Both public and private morality have come to accept birth control. The Catholic Church now accepts responsible parenthood and family planning, though only by abstinence and by the use of the 'safe-period'. Events have also shown that population pressure is not necessary as a stimulus to individual or social action. It was Malthus's successor at the East India College, the Rev. Richard Jones, who saw that it was not primary wants for food, but the secondary wants—capable of indefinite extension—which would constitute the brake on population increase. The intervention of birth control has not reduced the power of this brake; on the contrary, it has been enabled to act with greater effectiveness.

Further, when Malthus wrote, he was concerned especially with Britain, and with the possibility that rapid population growth might lower levels of living. Growth-rates were not, in fact, very rapid in relation to technological development at the time. To-day, in under-developed countries, growth-rates are frequently greater than 1·6 per cent annually. Further, the much more powerful means of reducing mortality may well raise growth-rates above 2 per cent per annum during the next two or three decades. At the same time, levels of living are so low that the first priority must be to raise them rather than to control population growth. Moreover, most economists regard that as possible. Though they view rapid population growth as a hindrance, they do not consider much slower growth an indispensable prerequisite for improving the levels of living in under-developed societies.

Higher levels of living are also necessary if population increase itself is to be re-adjusted. It might appear easier for birth control to spread in under-developed societies to-day than it was in the West during the nineteenth century. There is not the same degree of opposition from organized religion, and some governments have adopted policies for encouraging the use of birth control. But in the present context, the pressures in under-developed societies are not such as to induce many couples seriously to limit the size of their families. Though there is a generally 'favourable' attitude to birth control, positive interest often does not develop until couples have had four children. The fall in the birth-rate in Japan since the Second World War, though it has taken place against a background of official policy and of official and unofficial publicity, is not an example of what can be achieved by persuasion alone in under-developed societies. For in many essential respects, Japan is a highly developed society, with an advanced technology. Moreover, unlike India, Japanese tradition as such involved the control of population growth. Rapid economic and social change is needed if levels of living are to rise substantially in the face of rapid increase of population. Such change is also needed to provide the basis for new aspirations, without which the re-adjustment of population increase itself is unlikely to take place.

SCIENCE BROADCASTING IN SOUND AND TELEVISION

MR. A. B. OLDFIELD DAVIES discusses in his presidential address to Section X (Assembly of Corresponding Societies) the scope and form of science broadcasting in sound and television. Science broadcasting ranges from incidental references to scientific matters in magazine programmes like "At Home and Abroad" and "Matters of Moment" (sound) and "To-night" and "Panorama" (television) to more direct attempts at conveying scientific information by means of regular series of science broadcasts, the oldest established of which is "Science Survey". With a wide appeal because they deal with out-of-doors matters are various programmes on nature study, rural lore and astronomy. In addition to what may be called the staple fare of science programme' in television, of which the series "Eye on Research's is a regular ingredient made notable in 1960 by two special series intended as a prelude to the tercentenary celebrations of the Royal Society, there are the single, quite ambitious, even spectacular, programmes on subjects of current scientific importance once or twice a year.

In science broadcasting, as in all broadcasting, it is necessary to be clear as to the nature of the audience to be reached. Here sound broadcasting with its four domestic programme services has a range and flexibility denied to television which has not the same facilities for catering for minority audiences. The British Broadcasting Corporation's schools programmes, which pay considerable attention to science, are a clear example of catering for a particular audience, which looks and listens under conditions which are known, the pattern and purpose of the broadcast being the result of close consultation with various educational bodies. Here, too, the broadcaster can rely on the teacher to ensure that what is broadcast is likely to be grasped and understood. There is also consultation with outside bodies and individuals in planning adult programmes, but it is more spasmodic. There is no regular channel. Should there be a science advisory committee as there is a music or an agricultural advisory committee? Should there be in the British Broadcasting Corporation a department of science as there is for drama, music and religion? But science is not something which comes to life when it is performed. What is important is that there should be qualified scientists on the staff who are dedicated to the important job of communicating through sound and television broadcasting. Being a scientist is one thing, being professionally keen on communicating especially in terms that the masses understand is another. A person combining these qualities is not easily found. Yet more and more scientists are ready to communicate through broadcasting. In the six months of last winter more than a hundred different scientists took part in science programmes, not counting twenty-five scientists who broadcast in the Welsh language during the same period.

To assess the effectiveness of science broadcasting is not easy. The British Broadcasting Corporation's Audience Research Department helps to obtain the kind of information which a theatre or concert manager gets from his box office returns, or from the immediate reaction of the audiences to what is offered them. There are certain imponderable results which might become apparent over a period: general appreciation of the work of scientists, some notion of what they are after and the spirit that animates them, and a growing respect for knowledge as something good in itself.

THE CARDIFF REGION

The Cardiff Region

A Survey. Chairman of the Editorial Committee: Sir J. Frederick Rees. (Prepared for the meeting of the British Association held in Cardiff, 31 August to 7 September, 1960.) Pp. xv+222+24 plates. (Cardiff: University of Wales Press, 1960.) n.p.

IN the words of Sir Frederick Rees, the chairman of the editorial committee of "The Cardiff Region: a Survey", "During the last forty years great changes have occurred in the region and in our detailed knowledge of it. This survey endeavours to record some of these". The period of forty years is mentioned since the British Association last met in Cardiff in 1920. It also met there in 1891.

Thirty-two contributors, mainly from University College, Cardiff, have produced a volume full of information for the members of the Association. There are sections on landscape and climate; geology; botany; zoology; archæology; history; population; industrial structure; agriculture; the Welsh language; place-names; the literary tradition in Latin, Welsh and English; and educational institutions. It is impossible to mention all the contributors by name, but as all members of the British Association will see, they have done an excellent job.

The population of the city of Cardiff is now 253,000. Two million people live within a radius of thirty miles. Yet in 1801 Cardiff was a provincial market town with a population of only 1,870. As Prof. Brinley Thomas points out in the section on "The Growth of Population", Cardiff is there because of the Industrial Revolution; in particular, because of steam coal. In the early years of the Industrial Revolution the great centre in South Wales was Merthyr Tydfil, which in 1841 had a population of 35,000—three times that of Cardiff. But in 1841 the Taff Vale Railway, between Merthyr Tydfil and Cardiff was opened. There were soon extensions to the Aberdare Valley and the two Rhondda Valleys. Then Cardiff came into its own, for it is the natural outlet for the steam coalfields of South Wales. It soon developed the largest coal-exportation trade in the world.

The peak of the coal trade was just before the First World War. The population in 1911 was nine times the 1861 figure, and coal exports at nearly ten million tons had increased fourteen-fold in the same period. But although the peak came around 1911, the decline set in somewhat earlier, when because of inadequate port facilities in Cardiff, a large proportion of the coal trade was diverted to the nearby port of Barry. Barry's growth was even more sensational than that of Cardiff—from 494 in 1881 to 33,763 thirty years later. In common with other rapidly expanding towns, Cardiff at this time had a large migrant population. In 1911 only half the inhabitants had been born there.

But the growth of Cardiff is inseparable from the growth of the region, and the key to the region is coal. Coal has been worked in Glamorgan for hundreds of years, but until the eighteenth century it was on a small scale, chiefly at outcrops. Some was shipped across the Bristol Channel to Devon and Somerset.

The Industrial Revolution in South Wales started in the region of Merthyr Tydfil. In 1759 a partnership of nine people leased mineral rights in the area and started to build furnaces for smelting iron. One of them was Isaac Wilkinson, who introduced the process of coking coal for smelting iron in place of charcoal. The manager of the enterprise was John Guest, and he and Richard Crawshay, who later obtained control of a neighbouring area, founded the two great families of South Wales ironmasters—the Guests and the Crawshays.

The ironmasters were responsible for the building of the Glamorganshire Canal, from Merthyr Tydfil to Cardiff, and this Canal was the most important factor in the development of Cardiff up to 1840. Before that date not much importance had been attached to the exportation of coal, but in the 1840's, especially after a market was found for it in France, the steam coal from the Aberdare and the Rhondda Valleys began to dominate the region instead of iron. Pithead gears appeared up and down the pastoral valleys, and people moved in. By the beginning of the present century, the population of the Rhondda alone was more than 112,000. The tremendous demand for coal during the second half of the nineteenth century brought prosperity to the region, and led to the growth of the outlet port of Cardiff and later to the new port of Barry.

Coal may have become dominant in the mid-nineteenth century, but there were still plenty of ironworks. However, the development of steel technology in the 'sixties led to the closure of many of the smaller works and the growing dependence on imported ore led to re-siting closer to the sea or tidal estuaries.

The whole economy of the Cardiff region in the first part of the present century turned on coal, iron and steel, which is why the region was so hard hit by the depression in the 'thirties. World markets were contracting, and oil was a growing competition to coal. The result was mass unemployment and the hunger marches. Many left the region for the more prosperous Midlands and London. Between 1921 and 1931 there was a net loss of 230,000 people. The tide began to turn in 1935 when Richard Thomas and Co. bought the old steel works in Ebbw Vale and built there a new strip mill for the production of tin-plate. A trading estate was established, as part of a policy of diversification, and attracted a good many industrialists. By the end of the Second World War it was employing 17,000. By July 1955 unemployment in the region had fallen to 13,400—a peace-time record.

Coal and steel are still major industries in South Wales—the region produces 26 per cent of Britain's steel and has some of the largest and most modern works in Europe; but there are now many other industrial activities as well—aluminium, electrical engineering, synthetic fibres, for example.

The history, as opposed to the prehistory, of South Wales begins with the Roman conquest. The Romans made contact with the local tribe, the Silures, in A.D. 47 and fighting continued for thirty years or so. As usual, the Romans built forts and roads to facilitate the policing of the region. The remains of a typical fort is the Gaer, near Brecon. It comprised at first a rectangle of about eight acres with defensive earthen walls and ditches. Stone walls and gatehouses were added during the second century A.D. Towns grew up around the forts; for example, at Caerwent, where there was a regular street lay-out, public buildings, baths, houses and shops. Part of the defensive wall there still stands, 17 ft. high. At Caerleon, which became an important base about A.D. 75, there are also the remains of an amphitheatre in good condition.

From the departure of the Romans in the late fourth century to the Norman Conquest the history of the region is obscure, but during that time Christianity was introduced and the kingdom of Morgannwg established.

It was Morgannwg that opposed the Normans, under Robert fitz Hamon, Lord of Gloucester, during 1090–93, and he built a moated fort on the site that was later to be Cardiff. Fitz Hamon established feudal manors all over the plain close to the sea, but the mountains were left to the native Welsh.

Throughout the twelfth and thirteenth centuries Glamorgan was the scene of prolonged squabbles and wars, in which the Clare family and Llewellyns were greatly involved. The Clare family gradually gained control of the whole country but they lost it in 1314, and until the Act of Union under Henry VIII it was a pattern of mistake by the various Earls and their officials and rebellion by the Welsh. The new shire of Glamorgan, created by Henry VIII, had Cardiff as its county town.

To-day, Cardiff is the capital of Wales and has one of the finest civic centres in Britain. Adjoining the civic centre is the castle in 400 acres of parkland which was presented to the city in 1947 by the Marquess of Bute. Cardiff is still a major port for South Wales, and the dock area is an important part of the city. The notorious Tiger Bay is no longer what it was, and a recent film with that name was much criticized as not presenting a true picture of the city. Llandaff, a suburb of Cardiff, has been a religious centre for more than 2,000 years, and its fine cathedral dates from the twelfth century. It has been restored many times, and the most recent restoration after bomb damage in the Second World War includes the great choir arch bearing the Epstein "Majestas"—a figure of Christ in aluminium.

The Cardiff region has a remarkable variety of landscape in a small area. To the north is the South Wales Coalfield with its characteristic densely populated valleys—Rhondda, Cynon, Taff, etc.—reaching up into the moorland. Unlike the Midlands and South Lancashire, no one in the South Wales conurbation is far from open country. Farther to the north are the gaunt bare Brecon Beacons, nearly 3,000 ft. high. The steep northern scarp of the Brecon Beacons commands the valley of the Usk, in which the market town of Brecon lies, and to the east are the Black Mountains, less broken up, and more of a natural barrier than the Beacons. The Beacons, Fforest Fawr, the Black Mountains and the Usk Valley form the Brecon Beacons National Park.

To the north-west of Cardiff are the valleys of the Wye and the Monmow—a region rich in medieval buildings. There are Chepstow Castle on its limestone cliff, overlooking the Wye, the great Cistercian abbey of Tintern dating from the thirteenth century, and the bridge over the Monmow at Monmouth—the only one in the country with a two-storey fortified gatehouse. Closer to the sea, the land is flatter and intensively farmed. The lower Usk Valley is one of the best cattle-fattening areas in Wales.

All in all, the Cardiff region, besides fine scenery, provides things of interest to all sections of the British Association. For the physicists there is the Department of Physics at the University and the Post Office Radio Research Laboratory. For the chemists, works of Pilkington Bros., Imperial Chemical Industries, Ltd., and Monsanto. For the geologists, there is the South Wales Coalfield; and for the zoologists, the coast, dunes, caves and mountain lakes. No section is short of interesting excursions.

BRITISH ASSOCIATION PRESIDENT FOR 1961: SIR WILFRID LE GROS CLARK, F.R.S.

SIR WILFRID LE GROS CLARK, Dr. Lee's professor of anatomy in the University of Oxford since 1934, and Fellow of Hertford College, has been elected president of the British Association for the Advancement of Science for 1961. That year, the annual meeting will be held in Norwich.

Sir Wilfrid has achieved world fame as a human anatomist with special reference to palæontology and anthropology. Moreover, recognizing that the scientist should be interested not only in the science of discovery but also in scientific exposition and teaching, he has played a major part in the re-orientation of human anatomy as an academic discipline. This is exemplified by the organization of the new Department of Human Anatomy which was opened in Oxford last year (*Nature*, 183, 1572; 1959).

Sir Wilfrid is also director of the Medical Research Council Unit for Research on Climatic and Working Efficiency and a member of the Royal Naval Personnel Research Committee. His earliest years of professional work were spent in medicine. During 1920–23 he was principal medical officer of Sarawak, and later he was professor of anatomy in St. Bartholomew's Hospital Medical College (1927–29), followed by St. Thomas's Hospital Medical School until 1934, when he transferred to Oxford.

Such is the high esteem in which his work is held that Sir Wilfrid has given numerous special lectures at home and abroad, and he has been the recipient of several medals and honorary degrees.

(*Continued from page* 836)

together with mitochondrial counts revealed a number of important modifications occurring after feeding 3′-methyl-dimethylamino-azobenzene. When 2′-methyl-dimethylamino-azobenzene was substituted for the former dye, the changes were quite different in the early part of the experiment, but approached those observed with 3′-methyl-dimethylamino-azobenzene at later stages. Allard also described a number of electron-microscope observations made on pre-cancerous liver. Particularly interesting were some images suggestive of mitochondrial division and others indicating the appearance of small granules closely associated with ergastoplasmic membranes.

Some problems of mitochondrial regulation were discussed by F. Lynen (Munich) and by J. D. Judah (Philadelphia). Lynen examined in detail the theory, proposed a number of years ago by himself and by M. Johnson, to account for the Pasteur effect in yeast. The mainspring of this theory is that glycolysis and oxidative phosphorylation compete for the limiting amounts of inorganic phosphate and adenosine diphosphate available in the cell. Thus, glycolysis is depressed aerobically and enhanced by anaerobiosis or by inhibition of aerobic phosphorylation. While this interpretation is supported by the results of phosphate analyses, it cannot explain the decreased aerobic utilization of glucose. To account for the latter phenomenon, Lynen has suggested that the adenosine triphosphate, formed aerobically in the mitochondria, may not be as readily available to the phosphokinases of the glycolytic system as the adenosine triphosphate formed in fermentation. Investigations aimed at verifying this possibility have confirmed the existence of an adenosine triphosphate shuttle between the particulate and the non-particulate phases of the cells, but have also revealed that phospho-fructokinase appears to be inhibited preferentially to hexokinase in aerobiosis. At present, there is no satisfactory explanation for this finding. In the discussion which followed this interesting paper, the possible organization of the ground plasm was brought up for consideration by several speakers.

J. D. Judah described a series of recent investigations carried out in relation with the finding that several anti-histamine drugs act as powerful protectors against experimental liver injury. It was observed that these drugs inhibit the swelling of isolated mitochondria, as determined by a variety of conditions, and that they also inhibit the reversal of this phenomenon under the influence of adenosine triphosphate. In addition, anti-histamines were found to have no effect on respiration or on oxidative phosphorylation, but to inhibit the transfer of phosphate from adenosine triphosphate to phosphoprotein. When added to liver slices, previously incubated anaerobically, the drugs prevented the extrusion of water and restoration of the level of phosphoprotein which normally occur when oxygen is allowed to enter into the system. Judah put forward the hypothesis that the reversible changes in the water content of the mitochondria may be determined by changes in their content of phosphoproteins and that anti-histamines may prevent both types of changes by inhibiting a reversible protein phosphokinase.

In the general discussion which concluded the meeting, the necessity for a closer co-operation between electron-microscopists, histochemists and biochemists was stressed. It was also pointed out that further progress in our knowledge of the organization of the cell will be greatly dependent on the development, in all three fields, of new methods of greater accuracy and increased power of resolution.

C. de Duve

THE PHYSICAL SOCIETY

The principal contents of the 1959 Year Book of the Physical Society (pp. vi+124. London: Physical Society, 1959. 12s. 6*d*.), the fifth in the annual series, consists of the presidential address, entitled "Recent Trends in the Theory of the Ionosphere", which was delivered by J. A. Ratcliffe on May 21, 1959, following the annual general meeting of the Society, and the texts of the lectures and addresses given by the recipients of the various medals and prizes of the Society. Details are also given of the discourses delivered at the fifty-third Physical Society exhibition of scientific instruments and apparatus; the proceedings of the meetings of the Society during the period September 1958–June 1959; and the report of the Council of the Society for 1958. In addition, there are obituary notices of ten Fellows, including Sir Alfred Egerton, Prof. E. O. Lawrence, Prof. O. W. Richardson and F. Twyman.

In his presidential address, Mr. Ratcliffe gave a survey of recent ideas concerning the formation of the upper part of the ionosphere, known as the *F* layer. From measurements of the atmospheric density at great heights and computations of the electron distributions, it would appear that the layer is produced by the absorption of a solar ionizing radiation in atomic oxygen, which is distributed through the atmosphere as it would be if mixing were nearly complete up to heights of about 400 km. at least. When the radiation is incident normally, the absorption coefficient of the radiation is such that electrons are produced most rapidly at a height of about 180 km. Small alterations in the amount of mixing can produce marked changes in the electron distribution, and changes of this kind could be the cause of the observed winter anomaly in middle latitudes.

The forty-third Guthrie lecture, which was delivered by Sir Harrie Massey on April 8 at Oxford, was entitled "Collisions", and was confined to a discussion of a selected number of atomic collision phenomena including the elastic and inelastic collisions of electrons and of positrons with atoms, recombination and charge transfer processes in the upper atmosphere, and the dissociation of molecular ions by impact with gas atoms. The subject of the fifteenth Charles Vernon Boys Prize address given by Dr. D. West, of the United Kingdom

Atomic Energy Authority, Harwell, was a description of the method of observing π-mesonic X-rays. The work discussed was carried out on the Liverpool synchrocyclotron during 1952–56 and the main item of measuring equipment was a Hutchinson–Scarrott type kicksorter. It is most interesting, therefore, to find that the thirty-sixth Duddell Medal addresses, which follow Dr. West's article, were delivered by G. G. Scarrott on the application of computer techniques to nuclear physics instruments and by G. W. Hutchinson on 'memories' for nuclear physics.

In 1959 it was the turn of the Physical Society to arrange for the delivery of the Parsons Memorial Lecture, and Dr. C. R. Burch was invited to be the lecturer on October 22, 1959, at the Science Museum, London. He chose to speak about aspheric imaging systems and described the work in this field carried out by the University of Bristol's Optical Group during the past twenty years. Under Dr. Burch's inspiring influence, his devoted band of research workers, all of whom he proudly mentions by name and with affection, have made, many with their own hands, optical instruments of new and advanced design. Advanced testing methods, aspheric reflecting microscope design and manufacture, meniscus-Schmidt camera design and manufacture, cone-cylinder and screw interferometers, and several applications particularly in the biological field of these instruments are all touched on in Dr. Burch's lecture.

The subject of the twentieth Thomas Young Oration, given by Prof. R. W. Ditchburn on November 12, 1959, was also of an optical nature. He dealt with problems of visual discrimination, and described various methods of recording eye-movements and the analysis of involuntary movements. Eye-movements, both voluntary and involuntary, are of importance in contrast discrimination, and from the study of the discrimination of hue, it appears that in some conditions, normal subjects give reports usually associated with defective colour vision. The question as to how far the results obtained on the living eye are related to theories of retinal action is discussed with reference to electro-physiological measurements of impulses in optic nerve fibre of animals.

The lectures and addresses were intended for a very wide audience, and are extremely well and clearly written. They deal with specialist subjects, but their contents do not require specialist knowledge to understand them. The Year Book is a worthy addition to all science libraries.

THE COLONIAL DEVELOPMENT CORPORATION

THE annual report and statement of accounts of the Colonial Development Corporation for the year ended December 31, 1959*, the first to appear over Sir Nutcombe Hume's signature as chairman, follows the general style of Lord Reith's recent reports. Eighty-eight continuing projects are reported, as against seventy-seven the previous year, including fifteen new projects totalling £13,184,000, of which four have been removed from the list, and £4,046,000 further investment in existing projects was approved. Of the continuing projects, representing £90 million, of which £60 million has been spent, 45·2 per cent were concerned with utilities, 43·1 per cent with primary production and processing, and 11·7 per cent with commerce and industry, the corresponding figures for 1958 being 46·9, 40·8 and 12·3 per cent, respectively. No capital has yet been raised from outside sources, nor has any attempt been made to do so. Although the Corporation is now well established and its revenue is increasing, its present capital structure is unsuited to raising outside capital except with the Government's guarantee, but if the recommendations of the Sinclair Committee are adopted it should be much easier to devise a form of capital which would find purchasers among private investors without such a guarantee. The Corporation, however, is nearing the end of the resources it can draw from the Government, and further capital may soon be needed if it is to go forward.

The report emphasizes the importance of the correct adjustment of the relation between the highly industrialized countries and the under-developed countries of the world; and in these territories, for which the United Kingdom Government is responsible, the Corporation is in a unique position to assist in finding a solution to this problem. Even when money and technical aid are available, the capacity to put them to the best use is often lacking, and the Corporation has now built up an organization staffed by experienced people and designed for this very purpose. Their fitness for the task is shown both by the success now being achieved by the Corporation and by the fact that commercial interests, which have been hesitant to participate in risk ventures in territories the political and economic future of which was uncertain, have been reassured when the Corporation has been ready to be associated with their investment.

To assist in securing the maximum use of the Corporation's experienced organization in Great Britain and abroad, the chairman is leading a mission of the general manager and all six regional controllers to Washington to discuss the possibilities of the Corporation working for the International Bank, the International Finance Corporation and the Development Loan Fund. To-day the Corporation is well equipped to make contact with and examine new projects anywhere in the present or former dependent territories, to negotiate or assist in negotiating the terms of investment, to arrange for the management of the project and to watch over its progress. Almost all its capital of £130 million is now committed, and the value of products by direct projects and associated companies in 1959 amounted to about £18 million, much of which contributed to the export trade of the countries concerned. The stimulation of other development caused by the Corporation's example and initiative is more difficult to assess, but the report cites as examples new housing enterprises and ideas due to the Malaya Borneo Building Society and housing schemes in Africa and the Caribbean, and new standards for large-scale agricultural enterprises in Borneo set by Borneo

Abaco, Ltd., in introducing two new crops (cocoa and oil palms). The report also stresses the way in which opportunities are taken for partnership with private industry and association with local interests, and apart from stressing the importance of public relations and encouraging both at home and overseas a correct understanding of the Corporation's purpose and work, the report contains two interesting sections discussing various aspects of management and training schemes which merit separate consideration.

ECHO-SOUNDING EXPERIMENTS IN THE BARENTS SEA

NEARLY all large fishing vessels carry echo-sounders for locating fish. A 'ping' of sound is sent down into the water, and any fish between the ship and the sea bed give echoes which can be detected. In the case of vessels trawling for cod, it is fish within a few fathoms of the sea bed which are of interest, and because of the short separation in time between the echoes from these and the much stronger echo from the sea bed, certain difficulties arise. These have to a large extent been overcome by displaying the echoes on a cathode-ray oscilloscope, arranged to present echoes from near the sea bed on an expanded scale.

A recent booklet contains five papers concerned with the use of such equipment*. They cover the identification and measurement of the echoes, the relationship of the number and size of echoes to the catch of fish, the measurement of the strength of echoes from individual fish, practical and theoretical work on the properties of the equipment, and its use for surveying the distribution of fish on the fishing grounds. Taken together, they form a comprehensive survey of the characteristics and use of the equipment considered primarily from a practical point of view.

One is particularly struck by the high correlation between the count of echo signals, that is, the sum of the strengths of each echo during a trawling run, corrected for depth, and the number of fish caught. The correlation coefficients are in the region of 0·9, in spite of the necessarily rather crude methods of echo measurement.

In the past, much of the information required for systematic design of echo-sounders for fish detection has not been available. Design has been based largely on the properties of previous models known to give reasonably satisfactory results, followed by sea trials and alterations as required. The third paper describes an attempt to obtain some of the necessary basic data. The echo strength given by (dead) cod of different lengths has been measured and compared with the echo given by a standard target, so that the target strength of the cod is known in absolute units. The water-borne noise has been measured as a function of ship-speed and water-depth (though unfortunately only in terms of received voltage without the sensitivity of the receiver being known). The information about the target strength of cod is of universal application, and that about the water-borne noise allows the prediction of the performance of this particular sounder over a wide range of conditions.

The checking of the performance of equipment under working conditions is highly desirable, and helps to give one confidence in both the equipment and one's methods. The first part of the fourth paper describes checks of the beam pattern and of the variation of echo-strength with depth. Such checks have been made on many other acoustic devices, and since in the present case they also agree with theoretical expectations within experimental accuracy, the fifteen pages devoted to this work seem excessive.

In conclusion, these papers describe a great deal of careful work, mostly 'in the field', and form a very valuable contribution to the subject.

ORIGIN OF TEKTITES

By PROF. H. C. UREY, For.Mem.R.S.

University of California, La Jolla

LAST January, Dr. G. Baker[1] criticized in considerable detail my suggestion[2] that comet heads colliding with the Earth heated the surface to the melting point and spread small fragments of glassy objects to great distances and that these objects are tektites. I believe these objects have compositions which are not greatly different from some of the more acid terrestrial rocks, but that no source of sufficiently high temperatures to melt these materials is known to be present on the Earth's surface or somewhat below the surface. My communication was written to suggest a possible source of high temperatures. I really thought everyone who had worked on this problem would be pleased to consider a mechanism by which terrestrial material could be melted and scattered to great distances even though it did not necessarily answer all questions. This was certainly not true. I have thought over Dr. Baker's very thoughtful criticisms and would like to make a brief reply.

Dr. Baker is quite right about tektites not being spaced some 50 million years apart in age, but Prof. Z. Kopal very soon pointed out to me that cometary collisions with the Earth were probably ten or more times as frequent as I had assumed. I have not troubled to correct this incorrect estimate, for it was very uncertain in any event. We probably have only the most approximate ideas in regard to the numbers of non-luminous comet heads moving in the solar system; and comet heads must certainly collide with the Earth from time to time and should produce some effects which we could look for, and they should produce an effect of sufficient magnitude possibly to melt bits of glassy materials.

Also, Dr. Baker is right about the orientation of tektites during flight through gas. The stable position is motion through the gas with a maximum surface exposed in the direction of flight.

Dr. Baker accepts the conclusion that a swarm of objects of very considerable mass is required if such a swarm is to remain as an entity in the field of the Sun, and he tries to account for a large loss of this mass by abrasion during flight through the air, erosion after arrival at the Earth, and destruction by birds and men. If we postulate very many small masses, say, of millimetre sizes, then it is difficult to answer the first objection. But 100 gm. per cm.^{2} over an area of 5 million km.^{2} is 5×10^{12} tons, and hence we must assume a very large fraction of very fine material in order to account for its destruction in this way. The total energy of this mass of material, using his area of 5×10^6 km.^{2} (2×10^6 square miles) and a thickness of 100 gm./cm.^{2} and a velocity of 20 km. per sec., is 10^{31} ergs. This is equivalent to about 10^{10} ordinary Second World War atom bombs, or 2,000 per km.^{2}. The energy per cm.^{2} is 2×10^{14} ergs. The heat capacity of the atmosphere is about 10^{10} ergs per cm.^{2} and thus very high temperatures would be produced. Possibly such energetic processes occurred over southern Australia some 5,000 years ago, but also some evidence of it might remain. Possibly my scepticism based on inadequate knowledge is not unjustified.

The etching experiments with 4 per cent hydrogen fluoride do not seem to be very appropriate as a test of chemical erosion, since this reagent is used to dissolve rocks of all kinds and is known to be a very effective chemical for such purposes, since it converts silicon dioxide to gaseous silicon fluoride. Carbon dioxide and water is the usual erosion acid in Nature and it is much milder in its effects. But tektites have persisted on the Earth since the Eocene apparently, and during this long period should have been exposed to all the types of erosion that occur in Nature and they still have survived. Also tektites are abundant in the Philippines and other tropical humid regions and are fairly well preserved. The erosion of a layer of tektites of 100 gm./cm.^{2} from the southern Australian continent in 5,000 years does not seem probable to me, especially in view of the fact that, as Dr. Baker emphasizes, some of these objects are beautifully preserved. In fact, most of those that I have seen are so preserved. Could this vast amount of material of a very resistant kind have disappeared so completely in a short period of time? It seems improbable to me that both this great and complete destruction of so much material and the perfect preservation of specific samples under essentially similar conditions could have occurred.

Again, birds and men cannot dispose of such quantities of material, or even a small fraction of it, in so short a time, and it would seem likely that tektites would have become distributed over the whole of Australia instead of being limited to the southern part if such agents moved any important amounts of these materials.

But my mention of the swarm of objects and its elimination was very brief. If we are seriously to assume the existence of such a massive swarm, we must consider whether it would not have accumulated due to its own gravitational forces into a more compact object and hence have arrived at the Earth as such. In this case it approximates to the cometary model, or to a large meteorite model, and then we are back to scattering materials over vast areas. However, with these models it is unnecessary to assume a layer of 100 gm./cm.$^{-2}$, since this estimate depended on the extended cloud model and its stability in the Sun's field; also the energy dissipated, while very great, would be more limited in area and might well initiate volcanic or flooding processes, for example, which would obscure the location of the collision site.

But we are learning more about these objects. It is now found[3] that they do not contain aluminium-26, which was previously reported. There is no evidence that they have been exposed to cosmic rays. If they came from space in a swarm, the time in space was very brief. They may have come as a large compact object or they may have come from the Earth. Also, the potassium-40/argon-40 ages have been determined[4], and it is found that these ages for all tektites of south-east Asia and Australia are the same within the limits of error, namely, 610,000 ± ~ 50,000 years. The ages from geological studies that Dr. Baker mentions might be in agreement with this age for all these objects with the exception of the age of the australites, which he estimates as 5,000 years or "definitely Holocene". The potassium-40/argon-40 ages are calculated assuming that complete degassing took place at some time in the past. The consistency of the ages supports this, though one could wish that the variations, either real or due to observational errors, were less. If the age of 5,000 years given by Dr. Baker and that of 610,000 years given by the potassium-40/argon-40 ratio for the australites are correct, a degassing occurred 610,000 years ago, but delivery to Australia occurred much later. One wonders how and where that heating process occurred and where the objects were kept in the refrigerator free from cosmic rays since that time? I really am most reluctant to assume that the carefully considered age of the australites is wrong, but if they arrived 610,000 years ago it would greatly simplify our attempts to arrive at a satisfactory model. If the differences in geological age estimates and the potassium-40/argon-40 ages for all these groups of tektites are real, then similar questions in regard to the heating and cooling histories can be raised in regard to all of them.

If the agreement in potassium-40/argon-40 ages is significant—and I believe it is—a very great and extensive process must have produced these objects and we must all think again about the entire problem.

Did they come from the Moon? Could a collision of an object with the Moon splash them off in such a closely related pattern that they would all fall in these close patterns[5]? But would all such collisions produce such closely controlled conditions, or would they miss the Earth occasionally or, in fact, usually, and thus on a second, third or the *n*th pass fall all over the Earth? My answer is that they most probably would be very widely, and in fact uniformly, scattered over the Earth[6].

However, it has always been a puzzle to me that terrestrial surface materials containing appreciable water should melt into objects having so little water. Why did they not melt into pumice? But I have only tried to suggest a source of heat for melting this material and scattering it over great distances. It seems more reasonable to try to fashion some hypothetical process to produce them from known terrestrial materials, which they resemble in many ways, than to assume that they come from other places that we know so little about. Must we fashion another planet to produce their chemical composition, and then if we cannot find ways to melt these materials on Earth, why do we think they could be melted elsewhere ? If geologists will find a volcanic process which will produce these objects from appropriate terrestrial materials, such a solution would be the most satisfactory of any that I could imagine. (Mr. Paul Lowman mentioned this possibility to me in conversation.) But a volcanic process distributing material in limited regions over south-east Asia and Australia within a circle of 8,000 km. diameter would be most remarkable.

On the other hand, cometary collisions should occur occasionally, they should be very energetic, and their volatile constituents should supply a mechanism for propelling materials out of the atmosphere and to great distances, and the agreement in the potassium-40/argon-40 ages would be understandable. It could have been a single collision near the centre of this area, instead of multiple but nearly simultaneous ones as suggested previously.

It is nearly three years since my suggestion on the cometary origin of tektites appeared in *Nature*. I wish to thank Dr. Baker for raising the problem for public discussion and am only sorry that he did not do so earlier. Progress in resolving differences of this kind can be made most expeditiously by a public discussion of this kind in which all interested parties, including the one whose work is criticized, may know what doubts are being entertained.

ISOTOPIC COMPOSITION AND TEMPERATURE OF FORMATION OF ANTARCTIC SNOWS

By PROF. E. PICCIOTTO
Université de Bruxelles (Expédition Antarctique Belge, 1958)

X. DE MAERE
Service Météorologique de la Force Aérienne de Belgique (Expédition Antarctique Belge, 1958)

AND

I. FRIEDMAN
U.S. Geological Survey, Washington

IN an earlier communication[1], variations in the isotopic composition of the oxygen in falls of snow collected during 1958 at the Belgian Antarctic Base (King Baudouin Base, 70° 26′ S., 24° 19′ E.) were shown.

We intend, here, to present the variations in the isotopic composition of the hydrogen contained in the same samples.

The analysis of the aerological radio soundings carried out at the King Baudouin Base in the course of the International Geophysical Year[2] has enabled us to estimate the temperature range in the cloud corresponding to each snow-fall. This is, to the best of our knowledge, the first attempt carried out with the view of establishing a direct correlation between the isotopic composition of a snow-fall and its temperature of formation. The interesting results obtained in this field up to the present[4,5] originate from average samples representing accumulations over several months, or even years.

Variations of the Deuterium : Hydrogen Ratio

The ratio deuterium : hydrogen has been measured at the U.S. Geological Survey, Washington. The mass-spectrometric methods used have already been described[6].

Fig. 1 shows the variations of the deuterium : hydrogen ratio in the course of 1958. Each point represents an individual sample. The composition of the hydrogen is expressed as percentage variation of the deuterium : hydrogen ratio with respect to a conventional standard (standard mean ocean water). The variations of the deuterium : hydrogen ratio present the same characteristics as those of the oxygen-18 : oxygen-16 ratio previously discussed[1]; but their amplitude is 10 times larger[3]. Thus, summer snows are, in the average, 10 per cent richer in deuterium than winter snows. The maximum relative variation in the deuterium content is 20 per cent.

Fig. 2 shows the variations of ∂ (oxygen-18 : oxygen-16 ‰) with respect to Δ (deuterium : hydrogen per cent). As a first approximation, all the points are grouped about a straight line of equation : $\partial = 0{\cdot}8\,\Delta + 1{\cdot}8$. It appears that some points corresponding to August and September, that is, the end of winter, form a separate group.

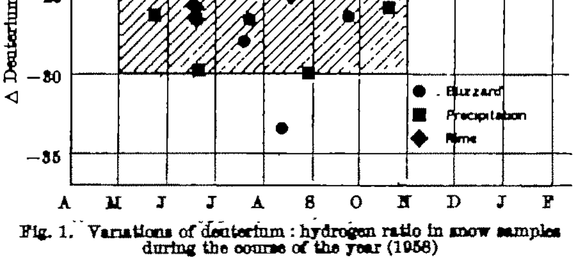

Fig. 1. Variations of deuterium : hydrogen ratio in snow samples during the course of the year (1958)

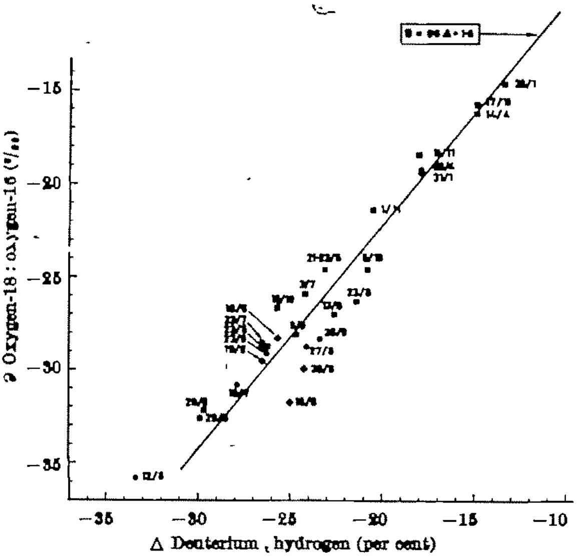

Fig. 2. Deuterium : hydrogen ratio compared with oxygen-18 : oxygen-16 ratio in the same sample. Same symbols as in Fig. 1. The date of collection is given for each sample. Oxygen isotopes data from Gonfiantini *et al.* (ref. 1)

Isotopic Composition and Temperature of Formation

In order to estimate the range of the temperature of formation of every fall of snow, we have noted from the radiosonde data the temperature at the base and at the top of the cloud at the moment of precipitation. This temperature is well defined in the fortunately frequent case of thin stratiform clouds with no higher cloud sheets. In the case of rime deposits, the temperature at a height of 1 metre above ground was taken. Drift-snow samples were excluded.

Table 1 shows the information obtained from the aerological soundings.

Fig. 3 shows the isotopic composition of the oxygen in each fall, with respect to the temperature-range in the corresponding cloud sheet. The straight line corresponding to the mean temperature of the cloud has been traced. There is seen to be a remarkable correlation between ∂ oxygen-18 and the temperature of formation of the precipitation, T.

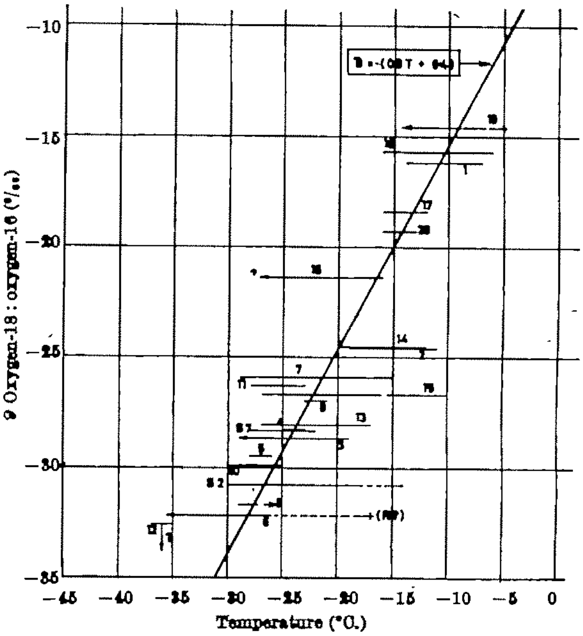

Fig. 3. Isotopic composition of oxygen in snow falls with respect to the temperature in the corresponding cloud sheet. Sample numbers refer to Table 1

The equation connecting ∂ and T is:

$$\partial(\text{oxygen-18}) = -(0{\cdot}9T + 6{\cdot}4)$$

An equally precise correlation has been found to exist between Δ (deuterium) and T, and is represented by the equation:

$$\Delta\,(\text{deuterium}) = -(0{\cdot}8T + 8)$$

The isotopic compositions ∂ and Δ essentially depend on the temperature of formation, and appear, at first sight, to be independent of any other condition such as the cloud height or the type of precipitation.

The very marked seasonal effect, and the very rapid transition from the 'isotopic winter' to the 'isotopic summer' (Fig. 1), may be clearly interpreted by referring to Fig. 4, which presents the mean monthly temperature of the air with respect to its height, in the atmosphere above King Baudouin Base. The known polar climatic characteristics very clearly

* Oxygen isotopes from Gonfiantini (ref. 1).

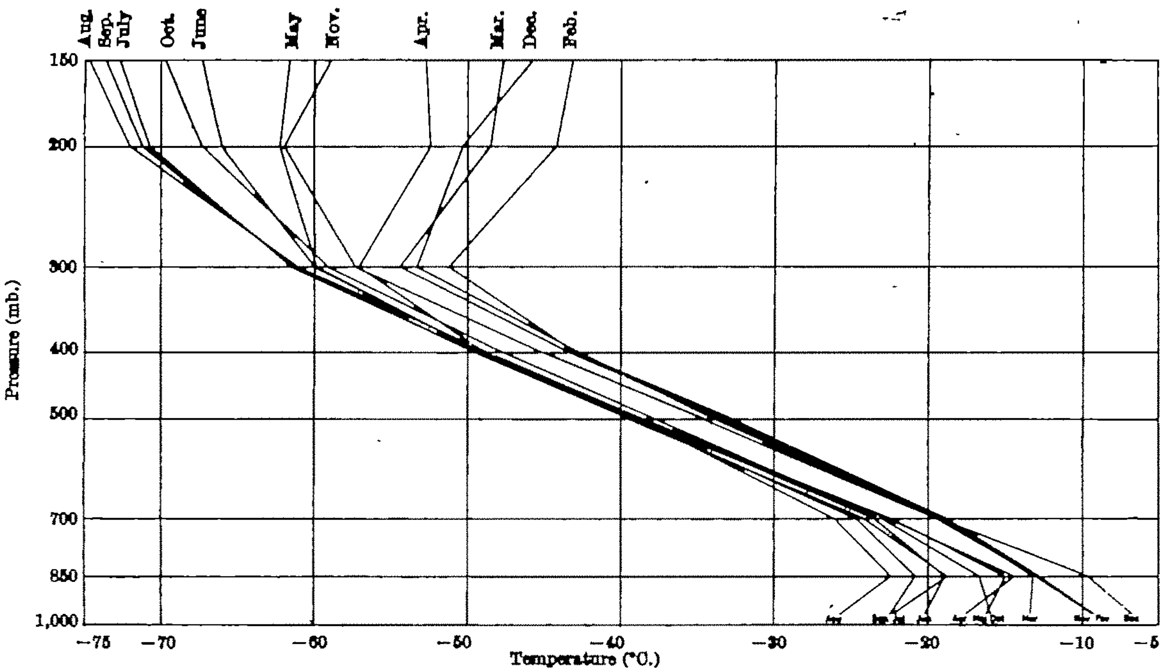

Fig. 4. Monthly mean temperatures from upper-air soundings at King Baudouin Base—1958

discussed in a recent article by Wexler[7] are found here. It is clear that the temperatures of the middle troposphere in which the precipitating clouds form are closely grouped about two mean values, and that these temperatures pass from the mean summer to the mean winter values in two abrupt jumps—between March and April, and between October and November. These two periods correspond very well to the abrupt variations in the isotopic composition of the precipitation (Fig. 1). As this behaviour of the tropospheric temperature is characteristic of the antarctic climate[7], it is to be hoped that the type of isotopic variations observed in 1958 follows a rule which will apply to other years.

On Fig. 4 is to be noted the wide dispersion of the ground temperatures, due mainly to the winter ground-inversion. This shows that ground temperature is not the best parameter to be used in work of this type.

In conclusion, the ratios oxygen-18 : oxygen-16 and deuterium : hydrogen in the snow-falls are seen to vary in a very similar pattern. These two parameters represent a veritable thermometer of the temperature of the middle troposphere, where the clouds causing the precipitation are formed. A variation of 1 deg. C. corresponds to a relative variation of about 1 $^{0}/_{00}$ in the ratio oxygen-18 : oxygen-16, and 0·8 per cent in the ratio deuterium : hydrogen—both values are well above the experimental errors of measurement.

The recent work of Dansgaard *et al.*[5] carried out on Greenland ice of known ages confirms that the isotopic composition of snow is conserved for at least several hundreds of years, even through compaction and transformation into ice. A very important application of these results would be a study of the recent climatic variations of the antarctic continent.

A full account of this work will be published elsewhere.

We wish to thank Dr. H. Wexler (U.S. Weather Bureau), Dr. W. Dansgaard (University of Copenhagen), Drs. E. Roth and G. Nief (C.E.N., Saclay) and Prof. E. Tongiorgi (University of Pisa) for helpful discussions.

VALENCE-BOND STRUCTURES: A NEW PROPOSAL

By Dr. J. W. LINNETT, F.R.S.*

Chemistry Department, University of California, Berkeley

In the simple valence-bond treatment of molecules such as CH_4, two electrons having opposed spins are assigned to each bond. A similar feature applies to such molecules as H_2O in which there are lone-pairs. It is assumed, in all these molecules, that there is a group of electrons of one spin and an *exactly* similar group of electrons of the other spin. For structures such as that of C_6H_6 or CO_2, which cannot be described adequately in such simple terms, the concept of resonance has been introduced, the structure being represented by a combination of two or more structures of the above kind. That is, each

[*] On leave from Inorganic Chemistry Laboratory, University of Oxford.

structure is made up of shared and lone pairs of electrons, and each structure has two identical sets of electrons, one being made up of electrons of spin $+\frac{1}{2}$ and the other of electrons of spin $-\frac{1}{2}$. It is the purpose of this communication to suggest some modifications of this approach, and, in particular, to propose a partial revision of our interpretation of the stability of such molecules as benzene and carbon dioxide, which is usually ascribed to resonance, and measured by resonance energy.

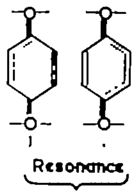
The modification that is proposed here was suggested by a consideration of the structure of the relatively stable 'radicals': nitric oxide, the *p*-benzo-semiquinone negative ion, Wurster's blue ion, diphenyl-picryl-hydrazyl, etc. In nitric oxide, there are five valency-shell electrons of one spin and six of the other. The first form a grouping in the molecule, which is represented by (I) and the second by (II):

I

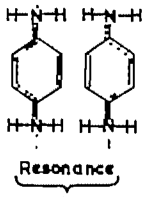
II

III

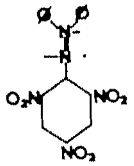
In both (I) and (II), there are four electrons (lone and shared) associated with each atom. So, if (I) and (II) are combined, the structure would be such that each atom possessed a shell of eight electrons made up of four of one spin and four of the other. Moreover, it is possible for each set of four to have a high probability of having a configuration which is nearly tetrahedral, though the two tetrahedra around each atom would not be superimposed. The combination of (I) and (II) may be represented fairly satisfactorily by (III), where —— signifies two electrons with opposed signs, ┘- - - one electron with one spin, and ····· one electron with the other spin[1]. On this basis the *p*-benzo-semiquinone negative ion, Wurster's blue ion and diphenyl-picryl-hydrazyl would be represented by (IV), (V) and (VI), along with other structures which are probably less important.



IV



V



VI

In all the above structures every carbon, nitrogen and oxygen atom has a shell of eight electrons, four of each spin. It is postulated that it is because such structures can occur and are important that the above substances show a high stability which may, otherwise, seem surprising. For example, if diphenyl-picryl-hydrazyl were to dimerize, there would be no net gain in the number of bonds, because the formation of the new bond would take place at the expense of the loss of the two half-bonds between the nitrogen atoms. The same is true for the semiquinone, as regards both polymerization and electron-transfer to produce the quinone and hydroquinone double negative ion. In (IV) and (V) above, it has been assumed that the structure is best described by a mixture of the two equivalent structures (resonance). This is required by the symmetry of the molecule.

This concept can be applied much more widely, but consideration will be limited here to the molecules O_2, CO_2 and C_6H_6. Oxygen, with twelve valency-shell electrons in all, could be imagined as adopting one or other of the structures (VII) and (VIII).

VII

VIII

In both, each atom has a shell of eight electrons, four of one spin and four of the other, and also for both there are four electrons involved in bonding. Which of these is going to be the ground-state? It is not surprising that (VIII) is, because, in this electron configuration, five electrons have the configuration ·O ⁝ O·, whereas the other seven have ⁝ O·O ⁝. As a result, the electrons, forming tetrahedral groupings, tend to be more widely separated on an average in (VIII) than in (VII). According to this approach, which is essentially an extension of the valence-bond method, it is just as easy to understand why the ground-state of O_2 is the triplet state, as it is on the method of molecular orbitals. The $^1\Delta$ and $^1\Sigma$ states of O_2 are 22·6 and 37·6 kcal. above the ground-state[2]. The latter resembles more closely the double bond in a polyatomic molecule (for example, ethylene) because the azimuthal positions of the electrons in the π_g orbital are uncorrelated (by spin correlation) in the $^1\Delta$ state, whereas they tend to be at the same azimuthal angle in the $^1\Sigma$ state. Thus, the adoption of structure (VIII) would appear to lower the energy about 35–40 kcal. relative to (VII), if (VII) represents a double-bonded structure of the type that exists in ethylene.

Now, for CO_2, resonance involving the structures =O=C=O=, ≡O—C≡O— and —O≡C—O≡ is usually supposed to occur. According to the present idea, there would be added:

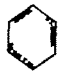
IX

X

XI

Of these, (IX) is likely to be the most important because it reduces the magnitude of inter-electron repulsion energy more than do the others. In (IX) the two bonds are analogous to the bond in (VIII). On this basis, it is not surprising that CO_2 is 36 kcal. (ref. 3) more stable than would be expected for the structure =O=C=O=. Moreover, the stabilization is not ascribed entirely to resonance but to the reduction in the inter-electron repulsion in (IX) as compared with that to be expected in =O=C=O=. Of course, it will still be true that a better description of the structure of CO_2 would be provided by resonance between (IX), (X), (XI) and the three conventional electron-pair structures. However, what is being suggested here is that it seems possible that (IX) is an important structure, and probably the most important one.

In a similar manner, benzene would be written as



XII

and the stabilization energy of 37 kcal. relative to a Kekulé structure (ref. 3) would be interpreted as being due, in large part, to a reduction in the inter-electron repulsion energy in (XII) as compared with that in a Kekulé structure involving the conventional double-bonds. It is of the same order as that found in O_2 and CO_2, and it is therefore not unreasonable to suppose that analogous effects are important in all these molecules. Further, the most simple-minded approach to electron–electron repulsion surely indicates that configurations which have high probability according to (XII) must, in truth, have a considerable probability relative to those indicated by the Kekulé formulæ. Yet, resonance between the two Kekulé forms sets a low probability on such configurations which separate spatially all the six electrons of the 'aromatic sextet' but nevertheless locate all in bond regions.

These ideas can be extended to other aromatic systems, chemical reactions, other free radicals, certain molecular compounds, all other systems which are usually represented in terms of resonance, and complex ions ; and these and other applications will be presented elsewhere. Here the account given has been qualitative, but wave-functions can be devised which correspond to the above structures and hence quantitative and semi-quantitative developments are possible. The method would be an extension of the valence-bond method. However, the wave functions could not be of the Heitler–London type but some modified or new form would have to be developed. This should not be difficult.

The proposal submitted here may be summarized in the following way. G. N. Lewis[4] stressed the importance of the electron octet. In all cases he treated it as made up of four pairs. It is suggested here that it is better to treat it as two groups of four electrons. When the two groups of four are similarly disposed, as they are in many molecules, the descriptions as four-pairs or two-quartets become identical. However, in other molecules and radicals, the employment of the two-quartets concept provides a satisfactory description, whereas the Lewis four-pairs does not. Therefore, it is proposed that the *octet* should not be treated primarily as four pairs but rather as a *double-quartet*.

CHROMOSOME PLOIDY AND RADIOSENSITIVITY OF TUMOURS

By LÁSZLÓ REVÉSZ and ULLA NORMAN

Institute for Tumour Biology, Karolinska Institutet Medical School, Stockholm

THE cell populations of animal and human neoplasms frequently show a considerable variation in chromosome number and deoxyribonucleic acid content[1,2]. It is not known whether there is any relationship between the chromosome number and the radiosensitivity of tumour cells. Work on the relationship between ploidy and sensitivity to radiation has been carried out on cells falling into the euploid series and derived from such biological objects as plants, fungi and arthropods[3]. If the effect of radiation on cell multiplication alone is considered, all reported observations indicate that radiosensitivity is greatest in the haploid cell and decreases more or less regularly with increasing ploidy. No direct extrapolations to neoplastic cells are permissible, however, since the predominant stem-line cell type is aneuploid in many tumours. The main stem-line number is frequently doubled, more or less exactly, in a smaller, second stem-line[1]. It cannot be predicted how a given aneuploid stem-line will react to radiation as compared to the doubled stem-line. Rearrangements occurring concurrently with, or after, duplication may, for example, render sensitive sites monosomic and make the cell more sensitive to radiation.

The problem was approached experimentally by determining the radiosensitivity of selected sub-lines of different ploidy derived from the same original tumour. In such material the findings can be interpreted with more confidence than would be the case when comparing independent tumour cell populations of different ploidy which, besides possible differences in radiosensitivity, may differ with regard to many, not necessarily relevant, other characteristics. An Ehrlich ascites tumour, designated *ELD*, also known under the synonym Landschütz sarcoma I or under the designation *LE* was used[4-6]. This tumour and its sub-lines were maintained in adult, heterozygous mice by intraperitoneal transfer of 0·1 ml. ascites diluted tenfold with sterile Ringer solution. During several periods of varying length, the cells were stored at −79° C. Chromosomes were counted on aceto-orcein squash preparations of material treated with colchicin[7]. More than 95 per cent of the *ELD* population is hyperdiploid with a modal chromosome number of 46. Cells with a doubled, hypertetraploid number occur at frequencies between 1 and 5 per cent.

Following Kaziwara's approach of 'immunoselection', that is, taking advantage of the increased

Table 1. PROPERTIES OF THE THREE SUB-LINES OF THE EHRLICH ASCITES TUMOUR

Property	Tumour line *ELD*	*ELT*	*ELTD*
Proportion of hypertetraploid cells	< 5 per cent	> 85 per cent	< 5 per cent
Modal chromosome number	46	92	46
Average cell volume*	1,368 ± 47μ^3	2,238 ± 67μ^3	1,370 ± 51μ^3
Average deoxyribonucleic acid per cell†	11·1 ± 0·5 × 10^{-9} mgm.	20·6 ± 1·1 × 10^{-9} mgm.	

* Determined according to ref. 9.
† Determined according to ref. 10.

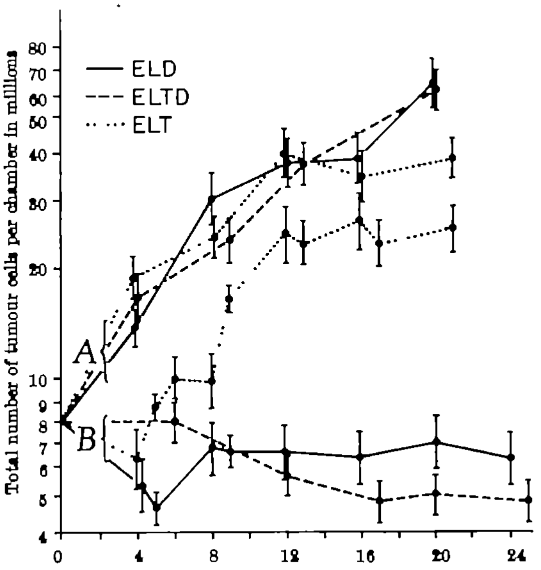

Fig. 1. Growth of hyperdiploid *ELD*, *ELTD*, and hypertetraploid *ELT* in diffusion chambers after inoculation of 8 × 10⁶ untreated cells and after irradiation with 2,000 r. The geometric mean and its standard error are indicated. The means have been calculated from 2–10 separate chambers in 1–8 separate experiments. The standard errors were obtained from calculations based on 17 duplicate and 6 triplicate determinations. *A*, untreated lines; *B*, irradiated lines

resistance of hypertetraploid cells to the homograft reaction as compared to the hyperdiploid cells[4], a predominantly (more than 85 per cent) hypertetraploid sub-line was derived from *ELD*, after homotransplantation of 20 × 10⁶ cells irradiated with 4,000 r. (ref. 4). The new line was designated *ELT* and had a modal chromosome number of 92. The X-ray dose damaged the majority of the cells irreversibly. Such lethally damaged cells may strengthen the homograft reaction considerably[8] and increase its selecting effect on the small viable remainder of the population. The ratios of modal chromosome number, average cell volume, and average amount of deoxyribonucleic acid per cell were approximately 1 : 2 when *ELD* and the first three consecutive transplant generations of *ELT* were compared (see Table 1 and ref. 4). In agreement with the findings of Kaziwara[6], hyperdiploid cells had a proliferative advantage over hypertetraploid cells in the absence of immunoselection[4] and the population of *ELT* shifted back gradually towards the predominance of hyperdiploid cells in the course of serial transfer with large (20 × 10⁶) cell doses. The tumour line derived from *ELT* after fifteen such passages, designated *ELTD*, was cytologically indistinguishable from the main *ELD* line.

In a series of experiments, 8 × 10⁶ untreated or irradiated cells of the three sub-lines were grown intraperitoneally within diffusion chambers of a modified Algire type[11]. The conditions of irradiation *in vitro*, the construction and sterilization of the chambers, and the method of introducing the cells are being published elsewhere[12]. 'Millipore' filters of *HA* type (Millipore Corporation, Bedford, Mass.) with a pore size of 0·5μ were used in order to protect the graft from the influence of cellular host reactions provoked by transplanted, irradiated cells[8,13]. Such reactions (inflammatory reaction, accelerated stroma formation, increased vascularization, homograft reaction, etc.) may have a stimulating or an inhibiting effect on tumour growth, and may therefore interfere with the testing of cellular radiosensitivity. The cell impermeable filter membrane permits the diffusion of soluble material, but prevents the pre-irradiated graft from having direct contact with host cells.

The cell content of the chambers was determined quantitatively at various intervals after inoculation. The technique is being described elsewhere[12]. The growth characteristics of the three sub-lines were closely similar when untreated. They differed clearly with regard to their response to radiation, however. After a dose of 1,000 r., the total number of *ELT* cells was consistently larger than that of *ELD* or *ELTD* at corresponding times during an observation period of 16 days. *ELT* cells, treated with 2,000 r. or 3,000 r., increased in number three- and two-fold, respectively, by the end of the third week after inoculation. No detectable increase of the *ELD* and *ELTD* populations occurred after treatment with the same X-ray doses. Irradiation with 4,000 r. inhibited the growth of all lines completely. The growth behaviour of the untreated cells and the growth curves after treatment with 2,000 r. are illustrated in Fig. 1.

These findings indicate that a difference exists between the radiosensitivity of tumour cell populations of common origin but differing in chromosome ploidy. The change of the radiosensitivity concurrently with the ploidy shift from a hyperdiploid to a hypertetraploid and, afterwards, again to a hyperdiploid dominance, implies that the difference in radiosensitivity can be related directly to the ploidy difference, and is not coincidental to the separate maintenance of the lines.

The question arises whether selection of polyploid cells in the course of radiation treatment may contribute to the development of resistance to radiation in animal or human neoplasms. Recent observations on the change of the deoxyribonucleic acid content associated with the development of resistance to radiation in human uterine tumours may favour this possibility[14].

A detailed report of this work will be published elsewhere.

We thank Prof. G. Klein for his continuous interest in these investigations and his stimulating criticism; and Dr. K. E. Hellstrom for advice regarding the cytological methods. PHYSICS

A New Plasma Confinement Geometry

As is well known, the strong synchrotron radiation recently predicted by Trubnikov and Kudryavtsev[1] from a plasma containing a magnetic field at thermonuclear temperatures makes it harder to design a thermonuclear reactor using the deuterium–tritium reaction, and practically impossible to design a deuterium–deuterium reactor. One way to get around this difficulty is to have no magnetic field in the plasma, so that the radiation becomes only a surface phenomenon instead of a bulk one. Of all the magnetic confining geometries at present known, theoretically only one has enough stability to hold a pure (that is, $\beta = 8\pi nkT/B^2 = 1$) plasma. This is the picket fence or cusped geometry[2]. Unfortunately, according to Grad[3], the cusps will be very leaky. Attempts have been made to construct geometries to avoid these leaks by closing the cusps on themselves (compare the most interesting papers by Braginski and Kadomtsev[4]). The same idea was proposed independently by Longmire and me some years ago under the name 'caulked picket fence'[5] (Fig. 1). These geometries involved current-carrying rings, disposed inside a solenoid having a longitudinal magnetic field. Quite apart from the topological impossibility of connecting leads or cooling to these rings without making contact with the plasma, the systems were unstable in their toroidal form because there was no rotational transform[6] in the torus axial field.

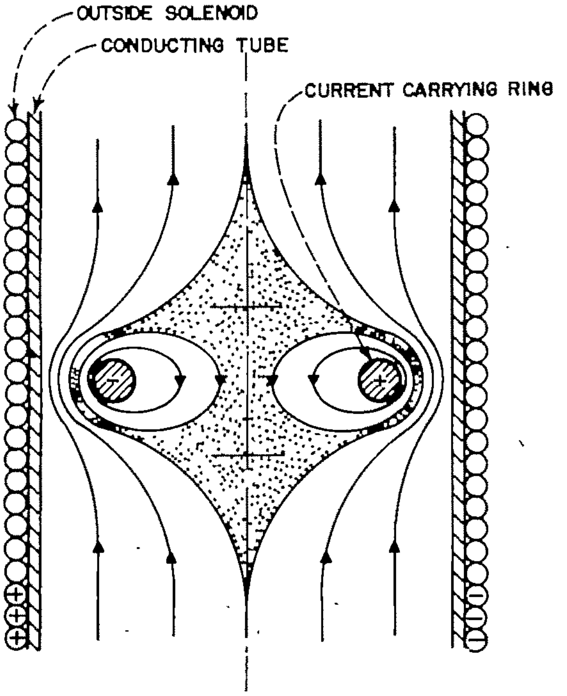

Fig. 1. Caulked picket fence geometry

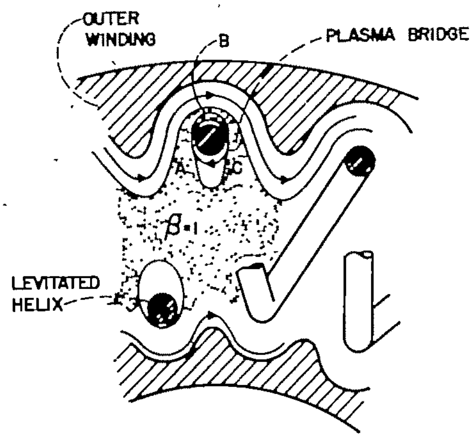

Fig. 2. Toroidal magnetic plasma confinement geometry. The inner spiral is continuous without connexions and floats in the magnetic field. The rotational transform of the field is not shown

During a re-examination of these old ideas, a new geometry (to be known as a helixion) has appeared, based on the helix, which appears to make possible stable $\beta = 1$ confinement with zero cusp losses in a torus. Furthermore, a linear helical system with $\beta = 1$ stable confinement, with cusp losses reducible to an arbitrarily small fraction of the confined plasma in unit time, that can be operated by d.c. and cooled, seems to be possible.

The toroidal helixion is shown in Fig. 2. An external tight helical winding on the torus has linear current density j per unit circumferential length. An internal open helix has mean current density $-j$ (less than this will suffice but involves a sacrifice of the confined volume). The effect of this is to produce a chain of regions along the axis where the field is weakened (there are no neutral points), which are bounded on all sides by magnetic fields of positive curvature. In the limit of infinite plasma conductivity, these places could be occupied by plasma, and be completely stable. However, these regions have cusps—say, A and C which are bridged by a line B encircling the inner conductor. In the region of the bridge, the system has a curvature which is in the sense for hydromagnetic instability. In the old conception (ref. 5 above), it was believed that the regions of the bridge would, since the field there is much larger than that surrounding the main body of the plasma, be largely free from plasma, so that the hydromagnetic instability would convey a negligible amount of plasma to the wall. By reference to the cusp loss theory of Grad[3], the cusp acts at high β like a slit, of width 2δ, where δ is the plasma-field sheath thickness, from which the plasma escapes freely. We now see that line B becomes a connecting bridge (tongue in the words of Kadomtsev) of plasma, having a particle density n no less than that in the main $\beta = 1$ body, although its β can be much less than unity, since the bridge field can be much larger than that at the main $\beta = 1$ plasma surface.

Consequently, it is imperative to retain hydromagnetic stability in the bridge. The problem of the hydromagnetic stability of this region much resembles that of the stellarator, and it is safe to assume that there will be a limiting stable β, call it β_c, in the bridge. Then if B_b is the magnetic field in the bridge, B_1 at the surface of the main $\beta = 1$ region, the critical density for stability everywhere will be $n = \beta_c B_b^2/8\pi nkT$, $\beta_c = B_1^2/B_b^2$.

Note that the inclination of the helical winding imparts a shear to the field in the bridge region, which is beneficial for stability, increasing β_c, and that the axial component of the current in the helix imparts a rotational transform to the axial field which is essential for stability in a torus. The current in the helix must be produced by magnetic induction, so the operation is discontinuous. The quantity (reacting volume/wall area) increases with the scale, as does the decay time constant of the induced current, so it is advantageous to make the device large. The magnetic levitation of a plain ring in a torus has already been demonstrated experimentally in connexion with the toroidal hard-core pinch concept or levitron of Colgate and Furth[7].

So far, in this hypothesis we have $\beta = 1$ stable confinement, with no cusp losses. Only the plasma in the bridges and surface sheaths will give synchrotron radiation. However, it would be idle to pretend that this object is simple from the practical point of view. The discontinuous operation is a disadvantage and it is difficult to cool the helix.

For the extension of this idea to an open-ended helixion, consider the cusped region that could be occupied by a plasma in the vicinity of the neutral point produced by a straight current-carrying wire, in a transverse magnetic field. Such a region has two cusps which are bridged around the wire, and two cusps which connect to the outside world. The plasma region does not touch the wire. Now it turns out that as the inclination of the wire to the magnetic field is reduced, the cusped region shrinks, and ultimately vanishes, without touching the wire. For a uniform magnetic field of magnitude A, and a plasma in pressure equilibrium with a field αA ($\alpha < 1$), the cusped region vanishes when the angle between the axis of the wire and the field is $\cos^{-1}\alpha$. The proof must be reserved for a longer communication.

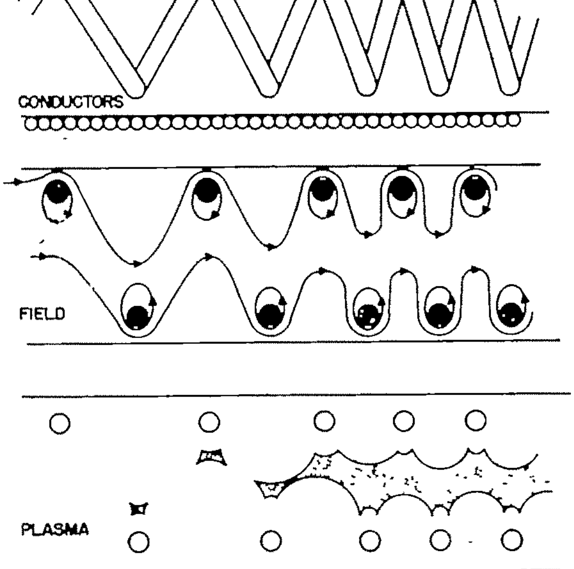

Fig. 3. Linear magnetic plasma confinement geometry with transition to outside connexion on the left. The spiral configuration of the field lines and the plasma bridges are not shown

Now consider a straight long solenoid having in it a helix as in the right-hand side of Fig. 3. The magnetic field is greatly reduced on the axis and is large between the helix and the wall. For connexion of the helix conductor to a source of d.c. current and for cooling, the helix is opened up, increasing the inclination of the turns to the axis, so that it ultimately emerges from the end as an axial conductor. The main bulk of the plasma has bridged cusps, and is connected to the outside world solely at the ends via a ring cusp. Now the losses from the end cusps are independent of the length, and the system can be made very long, since the solenoid can be supported magnetically. As with the torus, the system becomes energetically more profitable as the solenoid radius is increased. Most (possibly all) of the magnetic lines can be made to terminate at the ends of the system. This means that the mean stream of quiescent cross-field diffusion from plasma to wall can, if desired, be intercepted at the ends in the manner of a diverter[6].

Helpful criticism by H. Dreicer and T. H. Stratton is gratefully acknowledged.

Thermal Conduction in Mica along the Planes of Cleavage

A NUMBER of measurements on the thermal conductivity of mica perpendicular to the cleavage planes have been carried out in the past[1,2]. However, apart from the work of Jannetaz[3], which suggests that the thermal conductivity is highly anisotropic, no data appear to be available relating to conduction along the planes. We report here the results of some measurements, with heat flow along the planes of cleavage, on phlogopite, a type of mica which is effectively uniaxial and isotropic within the layers.

We employed two different experimental methods. In the first of these, the thermal conductivity was obtained directly using an absolute method[4]. A block of mica, which was built up from a large number of sheets, was cemented with 'Araldite' between two copper plates. The thermal resistance of the mica block was obtained by subtracting the resistance of the layers of adhesive from the measured overall resistance. The thickness of the mica block, perpendicular to the cleavage planes, was found from its weight; it was thought that a direct measurement of the thickness would have been inaccurate owing to the composite nature of the sample.

The thermal conductivity was also determined indirectly from the thermal diffusivity, using the apparatus described by Green and Cowles[5]. Temperatures were measured with 46 s.w.g. chromel-alumel thermocouples inserted in the composite mica sample. In calculating the thermal conductivity, a specific heat of 0·86 joule/gm. ° C. was assumed[6].

The results obtained by the two methods were in good agreement with each other. The indirect method yielded a value of 0·0190 cm.^{2}/sec. for the thermal diffusivity at 27° C., leading to a thermal conductance of 0·0163 ± 0·0009 W./° C. for a rectangular block 1 cm. long, with a mass of 1 gm. Using the direct method, this quantity was found to be 0·0185 ± 0·0018 W./° C.; within the limits of experimental accuracy, it showed no variation over the temperature range −85° to 35° C. Thus, assuming a density of 2·8 gm./c.c. (ref. 6), the values for the thermal conductivity corresponding to the two methods are 0·046 and 0·052 W./cm. ° C. respectively.

It is concluded that the thermal conductivity of phlogopite along the planes of cleavage is about 0·05 W./cm. ° C. This is an order of magnitude greater than the values which are typical for the perpendicular direction[1].

Measurement of Slip (*Ko*) and Viscous (*Bo*) Flow Coefficients of Permeable Solids

IT is usual to measure the slip (Ko) and viscous (Bo) flow coefficients of permeable solids by plotting $K = \frac{u_1 p_1}{\nabla p}$ as a function of mean specimen pressure $\bar{p}$, and using the slope and intercepts of the curve to find Bo and Ko. It is also possible to find Bo and Ko in one measurement (at a single $\bar{p}$), of K, p_1 (inlet), p_2 (outlet) and the centre-specimen pressure. By knowing that the mass flow:

$$Q_m = -\frac{MA}{RT} K(\bar{p}) \frac{\partial p}{\partial x}, \text{ that } K = a + b.\bar{p}$$

$$\text{where } a = Ko.\frac{4}{3}\sqrt{\frac{8RT}{\pi M}}$$

and $b = Bo/\eta$ (η is gas viscosity), and that the divergence of Q_m is zero (Z — axial flow only, that is, a rod or bar test-piece), a pressure distribution $p(Z)$ can be calculated; by putting $p(Z) = p(\frac{1}{2})$, that is, pressure half-way along the bar-length ($Z = L/2$), a/b can be found as:

$$\frac{\frac{1}{2}(p_1^2 + p_2^2) - p^2(\frac{1}{2})}{2\,p(\frac{1}{2}) - (p_2 + p_1)}$$

by measurements of pressures at three points, independently of flow. Since $K = b.\bar{p}\left[1 + \frac{a}{b} \cdot \frac{1}{\bar{p}}\right]$, by finding K from flow measurements, b can be found, and hence a: that is, Bo and Ko can be found.

$p(\frac{1}{2})$ = R.M.S. value, $\sqrt{\frac{p_1^2 + p_2^2}{2}}$, for the case $Ko = 0$, and $= \bar{p}$ when Bo is zero.

It is hoped to publish this method fully elsewhere.

ASTROPHYSICS

Temperatures reached in Electrical Discharges in the Solar Atmosphere

IN a contribution[1a] to the Institution of Electrical Engineers Convention on Thermonuclear Processes, of which a somewhat fuller account was published later in *Nature*[1b], I suggested that the electrical discharge theory of solar flares and the associated magnetic storms and auroræ led to the surprising result that the temperature of these discharges must reach values of the order of 100,000,000° K. somewhere between the Sun and the Earth's orbit. In another account[1c] of this work, I suggested that this need not come as too great a surprise, as temperatures of the order of 1,000,000° K. had been obtained some years earlier in electrical discharges in the laboratory (I. V. Kurchatov, Moscow, 1956), and for long have been known to exist in the solar corona.

Furthermore, a similar increase in temperature is observed when long electrical discharges are propagated down the corresponding, but lesser, density gradients in some stellar atmospheres—those of the combination spectra stars, such as *Z* Andromedæ and *AX* Persei, for example. In these the temperature is initially that leading to the ionization of the metals, hydrogen and helium, that is, probably of the order of 5,000° or 10,000° K. However, by the time the discharge reaches the outer regions of these stellar atmospheres, after periods of the order of 100–200 days, the discharge temperature reaches values of the order of 1,000,000° K. as lines of Fe X and Fe XIV appear in the star's spectra.

Though there was thus some additional theoretical support for the surprising conclusion to which the theory led when applied to these solar phenomena, it is satisfactory to learn that satellite observations made by the U.S. Navy scientists have confirmed[2] that these high temperatures do exist in the disturbances associated with solar flares. As I emphasized many years ago[1d], it is difficult to see how these high temperatures can be built up by any other mechanism than that of an electrical discharge.

Similar temperatures are reached in galactic electric discharges, and can be measured, as I have suggested, by the proposed 'cosmic gas-velocity thermometer'[1e], of which the basic conception is that these high gas velocities observed in stars and galaxies are always the result of electrical discharges, the velocities of these jets being linked closely with their temperatures[1f], in contradistinction to the assumptions often made in other accounts of these solar jets[2]. The only limit to the discharge temperature will be the onset of thermonuclear processes[1f].

On the electrical discharge theory of galactic evolution[1d,g] the main difference between the gas which ultimately forms Population I stars, and that which originally formed Population II stars, is that the former has been subjected to 'thermonuclear temperatures' of the order of 400,000,000° K. for a period of the order of 10–100 million years, during the formation of the spiral arms. It may be, therefore, that it is this difference which has led to the difference in the proportions of the heavier elements observed in these two stellar populations. It is not easy to visualize all the physical characteristics of electrical discharges on such a scale as that envisaged, but at present the value of n, the number of atoms per cm.^{3} of the galactic atmosphere, required to effect the observed chemical change in the time available, appears to be too high. However, it would be interesting to have comments on this suggested explanation of this difference between the two stellar populations.

The Sudden Discontinuity in the Orbital Period of *Sputnik* 4 Satellite

THE orbit of the fourth Russian Earth satellite soon after its late launching on May 14, 1960, was similar to the orbits of the previous *Sputniks*, as may be seen from the orbital elements shown in Table 1. A Tass News Agency report of May 17 indicated that there were two objects close together in orbit—the composite satellite itself, consisting of a 'space capsule' attached to an instrumental section, and the last stage of the launching rocket. The instrumental section included a transmitter or transmitters radiating on frequencies of 19·996 and 39·992 Mc./s., as measured at the Radio Research Station, Slough. The first radio directional observations from the United Kingdom were made at the Radio Research Station on transits occurring at about 1054 hr. and 1225 hr. U.T. on May 15. The first reported visual observation from Western Europe of the composite satellite and rocket was made from Meudon at about 0325 hr. U.T. on May 16.

The radio observations of the transmitting component made before May 19.0 indicated that the satellite was behaving normally, the nodal period dropping by about 0·3 sec./day. However, radio observations made after this time indicated that the satellite was reaching northern apex progressively later on each revolution, and by 1200 hr. U.T. on May 19 its transits were some 25 min. later than predicted. Interferometer observations made at the Radio Research Station indicated that the inclination of the orbit had not appreciably altered, and so an increase in orbital period was suspected. A comparison between predicted and observed apex times was made from transits before and after 00 hr. U.T. on May 19, and the differences have been plotted against the observed apex times (Fig. 1). The plot consists of two distinct linear distributions of points and the intersection of lines fitted to each group lies at 2357 hr. U.T. on May 18. The time of this observed discontinuity in the orbital period coincides very closely with the time of 2353 hr. U.T. at which, according to a Tass News Agency report of May 21, an attempt had been made to bring the 'space capsule' out of orbit. It is of interest to note that at the latter time the satellite was almost exactly at perigee position, the geographical co-ordinates of which were long. 60° E., lat. 54° N., and the path of the satellite lay across the whole breadth of the U.S.S.R. The slope of the plot after the discontinuity implies an increase of period of approximately 3 min. from about 91·2 min. to 94·3 min., and the elements of the orbit after this time are shown in Table 1.

Table 1. ORBITAL ELEMENTS OF *Sputnik* 4 SATELLITE

	Before approx. 00 hr. U.T. May 19	After approx. 00 hr. U.T. May 19
Mean nodal period	91·18 min.	94 26 min.
Semi-major axis	6,711 km.	6,861 km.
Eccentricity	0 004	0·026
Argument of perigee	+ 61°	uncertain
Inclination	64 89°	64 89°
R.A. of ascending node	254·3	254 3

At about 0741 hr. U.T. on May 19, the originally composite satellite was observed visually from Canada as two close components which are now slowly separating. The leading component has been identified by directional radio observations made at the Radio Research Station, Slough, as the transmitter section. Later observations indicated the presence of more than two components in approximately the same orbit as the transmitting section: visual observations on a total of five objects in this orbit have reached us.

The information available from the Tass report of May 21 indicates that the 'space capsule' was apper-

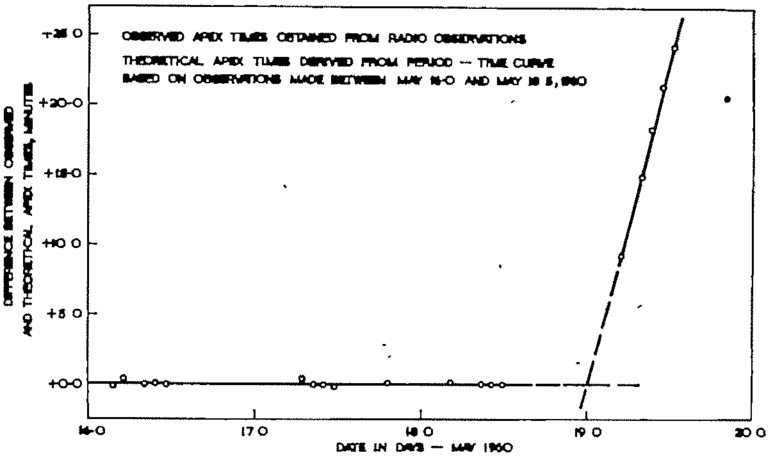

Fig. 1. Discontinuity in nodal period of transmitting component of *Sputnik* 4

ently intended to leave the orbit from near the perigee position by means of a retro-rocket system. The observed discontinuity in the orbital period of the satellite seems to suggest that the satellite was misaligned at the time of firing and, as a consequence, the retro-rocket placed both the capsule and the transmitting section into a higher orbit than that of the rocket.

OCEANOGRAPHY

Ocean Currents in McMurdo Sound

MEASUREMENTS of ocean currents in McMurdo Sound, Antarctica, were made during May and June 1959, by measuring the potential differences developed between three silver–silver chloride electrodes hung in the sea below the ice.

Initially the electrodes were placed in the sea at the same location to determine the contact potentials and to estimate their variations. The electrodes, labelled *N*, *W* and *S*, were then placed out, *N* 500 m. north and *W* 500 m. west of the third electrode *S* which was 5 km. from Scott Base (77° 51′ S. and 166° 48′ E.) and on a line bearing 200° from it. The electrodes were connected by cable to Scott Base where the potentials between adjacent pairs were recorded by a four-point Honeywell Brown recorder.

On magnetically disturbed days the records were too disturbed to be of use. The records from calm days were selected and the values recorded by each adjacent electrode pair were averaged over a whole day, thus eliminating the tidal effect, which was mainly diurnal, leaving the general ocean drift. Since the instantaneous sum of the *N–S* and *S–W* potential differences equalled the *N–W* difference, the averages found for the respective channels should agree likewise.

For the purposes of calculating the currents it was assumed that there was a uniform flow in a straight channel. After consideration of the formula derived by Longuet-Higgins[1] for flow in a semi-elliptical channel, it was assumed that the shape of the channel and the conductivity of the bedrock were in this instance not important factors. A value of 0·69 oersted was used for the vertical component of the Earth's magnetic field. The results of the analysis of 18 days records are listed in Table 1, giving a mean velocity of 7·5 cm. sec.$^{-1}$ in a direction 44° east of north. Short-term current meter readings were in general agreement with this mean. These results indicate a different direction of drift past Cape Armitage (from McMurdo Sound towards the Ross ice shelf) from that which has been observed during summer months[2].

Lead strip electrodes, placed on the surface of the ice, which was 2 m. thick, were tried also; but the experiment had to be abandoned before conclusive results could be obtained, although the few records obtained indicate that despite a larger contact potential it would be possible to get useful results.

A more detailed account of these measurements, together with associated hydrological and tidal observations, is in preparation.

GEOLOGY

Average Composition of Granites, the Genesis of Tektites, and Petrogenesis

THE recent article by Lovering[1], in which the average chemical composition of tektites was compared and contrasted with the average composition of terrestrial shales, calcalkaline granites and granophyres, involves an important question which is too frequently ignored. Comparison was made with the average bulk chemical composition of shales (78 analyses from Clark's Tables), granites (72 analyses quoted by Nockolds) and acid granophyric differentiates of basic magma (35 analyses available in the literature). As a basis of discussion, it may be assumed that the bulk chemical analyses are accurate representations of each of the 185 samples involved. Probably it is reasonable to assume that each of the 185 specimens was chosen by a competent geologist as a 'typical sample' to represent the rock-mass concerned.

The vast majority of granitic bodies which outcrop at the Earth's surface have received some qualitative but virtually no quantitative study. Thus, there are virtually no granite plutons for which anything like adequate information is available as a basis for determining the quantitative composition of the two-dimensional outcrop (representing the random section through the rock-mass). Even less is known about the three-dimensional composition and variability. At the present time, meagre quantitative data are available for a dozen or so granite plutons. In each case elementary statistical analysis demonstrates that compositional gradients occur in the bulk composition, and one or two 'typical specimens' constitute a totally inadequate sample upon which to base an estimate of the average composition of the target population of specimens comprising the entire pluton. Preliminary results for the 'older granite' of Donegal, Ireland, have been published[2,3] and additional more detailed analyses are in hand. Studies of variability in the Bahalda Road granodiorite (India), the Wollaston and Deloro plutons (Canada), the Beinn an Dubhaich granite (Scotland), and the Mourne Mountain granite $G2$ (Ireland) are the subject of a manuscript in the press.

Critical study of these six and several other granite bodies makes it amply clear that for any one granitic mass the arithmetic mean computed for a few 'typical specimens' yields a meaningless value in terms of the average composition of the entire volume of granite. The geologist who collects the 'typical specimens' almost certainly introduces a strong bias in his selection either involuntarily or voluntarily. Hence adequate sampling of a pluton does not require simply the collection of a large number of 'typical specimens', but involves the implementation of a sampling design adjusted to the individual characteristics of the rock mass (cf. Krumbein[4]). So far as is known, no entirely satisfactory sample has ever been taken for an entire granite pluton, so that the average composition of a body of granite cannot be stated accurately in any single case.

In view of the problem involved in assessing the bulk mineralogical and/or chemical composition of a single granite body, the arithmetic mean of bulk chemical analyses of single specimens drawn from 72 separate rock masses will produce a value having little or no precise relationship to the average composition of the target population for the 72 terrestrial plutons. However, if from a collection of hand-specimens derived from different plutons 72 similar samples are selected by a trained geologist, it is highly probable that the average of the individual chemical analyses will represent the average composition of the 72 specimens, but not of the 72 plutons represented.

Apart from the average composition, reasonably complete sampling in the few masses studied quantitatively shows that a large range in modal and normative composition occurs in each rock-mass. This is contrary to the impression given by the usual published ternary diagrams (both normative and modal) based upon one 'typical specimen' from each of a large number of complexes. In the latter case the points naturally cluster closely together (cf. Tuttle and Bowen[5]), and in the former are scattered widely on the ternary diagrams.

Hence, whether the composition of tektites is related to analyses of the 72 calcalkaline granites or the 35 granophyres may be interesting; even a very strong positive correlation does not indicate whether the tektites are related to the average composition of granite massifs of broadly calcalkaline affinities or to granophyric differentiates. Similar arguments apply with equal force when a few 'typical specimens' are employed to draw comparisons between the bulk quantitative composition of different rock-masses, and also when such samples drawn from different areas are employed as the bases of petrogenetic theories. However, in geological discussion considerable significance is usually attached to such average chemical and mineralogical values. This subject is developed more extensively, and illustrated by quantitative data, in a further manuscript awaiting publication.

Nomenclature of the Keuper Series

IN the announcement in *Nature*[1] of the most interesting results of the recent borings penetrating the Trias of the Cheshire Plain, the Director of the Geological Survey made certain suggestions for the nomenclature of the subdivisions of the Keuper Series which, if adopted, may result in considerable confusion. The Keuper Series has, in the past, been subdivided into Keuper Marl and Keuper Sandstone rather than into Upper Keuper and Lower Keuper respectively, although Wills[2] calls the latter usage the "traditional classification". Keuper Marl and Keuper Sandstone were originally what we would now call rock-stratigraphical units which have acquired a time-stratigraphical significance even though this is probably not justified in view of the paucity of fossils in the Trias and the weight that has to be placed on lithological correlation. Difficulties have not arisen to any serious extent, because the subdivisions of both stages of the Keuper have been in rock-stratigraphical units and have been applicable to quite large but distinct areas. It is also of importance that the terms Lower, Middle and Upper Keuper are in use in Germany which, after all, was the type area, and that, at the moment, there is uncertainty concerning correlations suggested by the flora and fauna of the Bromsgrove Keuper Sandstone with the Lettenkohle and the Muschelkalk of Germany and the Grés à Voltzia of Alsace.

The new subdivisions proposed for Cheshire are likely to be confusing because of the use before Keuper of the words 'Lower', 'Middle' and 'Upper', particularly with capital letters, which implies a time significance within the Keuper Series. For example, Lower Keuper Marl is intended to indicate a formation in the lower part of the Keuper Marl, that is, lower Upper Keuper. As pointed out above, Lower Keuper is not, in fact, now normally used by British stratigraphers to indicate the Keuper Sandstone, but to someone not familiar with the stratigraphy of the British Trias the term immediately suggests a marl in the Lower Keuper, that is, in the Keuper Sandstone. The same sort of criticism may be made of the other four subdivisions and of the term Upper Keuper Sandstone.

The provisional names suggested for the Keuper Sandstone raise additional difficulties. In the past[3,4], the Upper Keuper Sandstone has been the name given to what is now normally known as the Arden Sandstone[4], which truly belongs to the upper part of the Keuper Series. It is noteworthy that, to eliminate confusion, the term Arden Sandstone is used virtually exclusively nowadays. Furthermore, Hull[5] used Lower Keuper Sandstone to cover the whole of the Keuper Sandstone, and the use of Upper Keuper

Sandstone to indicate the upper part of the Keuper Sandstone is most undesirable.

Those who have been compiling the "Lexicon of Stratigraphy" have good cause to know the confusion which reigns as a result of the indiscriminate use of 'Lower', 'Middle' and 'Upper', and many similar examples in British stratigraphy could be quoted. It is to be hoped that the Geological Survey, particularly bearing in mind the German usage, will not now add new sources of difficulty at a time when it is widely agreed that there is great need for some simplification and clarification of the nomenclature.

[3] Brodie, P. B., *Quart. J. Geol. Soc. Lond.*, 12, 374 (1856).

[4] Matley, C. A., *Quart. J. Geol. Soc. Lond.*, 68, 252 (1912).

[5] Hull, E., "The Triassic and Permian Rocks of the Midland Counties of England", *Mem. Geol. Surv. U.K.*, 66 (1869).

THE Geological Survey of Great Britain produces geological maps distinguishing strata with particular lithological characters and ages; thus Chalk is singled out from other limestones and given a particular colour on small-scale geological maps; on larger-scale maps certain hard bands have been used to divide the formation into Lower, Middle and Upper Chalk; likewise, some argillaceous strata of widespread distribution containing marine fossils are now used to divide the Coal Measures into Lower, Middle and Upper Coal Measures.

In the recent article on Triassic Salt in the Cheshire and Shropshire Basin, it was shown that two horizons of Saliferous Beds would be used to divide the Keuper Marl formation into Lower, Middle and Upper divisions in Cheshire. This will replace the older division into Lower and Upper Keuper Marl, which was used, for example, on the 1958 edition of One-inch Sheet 97 (Runcorn) before the Upper Saliferous Series was known to exist[1].

The use in geology of saliferous horizons as indicators of the past existence of particular climatic conditions over wide areas is not new. Accordingly it is considered that Lower, Middle and Upper Keuper Marl are legitimate terms for the depiction of strata on the geological map, and that to describe such usage as "indiscriminate" is misleading. It is well known that the British nomenclature of subsystemic units is far from ideal; and from time to time the Geological Survey is obliged to accommodate new discoveries by division of time-honoured units, in the present instance the Keuper Marl. In making this particular decision, the names Lower, Middle and Upper Keuper Marl were considered suitable; and no alternative was considered, such as the invention of stratal names based on localities. Such a course may well be taken, however, when investigations are completed on the beds "provisionally called Upper Keuper Sandstone".

METALLURGY

Non-crystalline Structure in Solidified Gold-Silicon Alloys

EXCEPT for thin films deposited at very low temperatures[1], highly disordered arrangements of the atoms, similar to that of the liquid state, have never been observed in solid metals and alloys. For some metalloids, the bonding of which may actually be more covalent than metallic, such amorphous configurations have been retained in the solid state[2] by cooling from the melt with sufficient celerity so as to prevent formation of the equilibrium crystalline structures.

It is thus conceivable that such non-crystalline structures can be obtained for some, perhaps all, metals and alloys by quenching rapidly enough from the molten state. In the course of experimentation with the apparatus developed by us[3], an amorphous structure has been detected in a 25 atomic per cent silicon–gold alloy which was quenched from ~ 1,300° C. to room temperature.

The quenched alloy was studied by means of X-ray diffraction. A flake (area ~ 0·2 mm.^{2}; thickness ~ 10μ) was mounted in a Debye–Scherrer camera and exposed to copper K radiation. Intensity (on an approximately linear scale), as obtained from the film with a microphotometer, is plotted against sin θ/λ in Fig. 1.

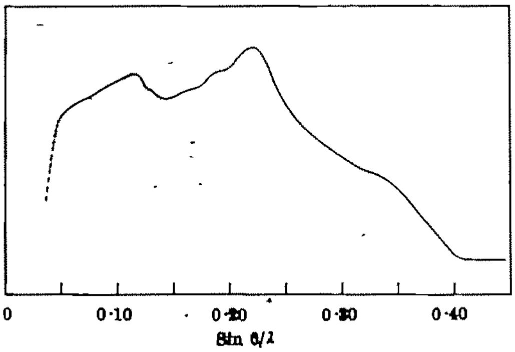

Fig. 1. X-ray diffraction pattern of gold–silicon alloy

It is to be emphasized that the amorphous foil is quite unstable at room temperature (and it is entirely possible that some decomposition could have occurred during the 3-hr. exposure). The decomposition products detected after 24 hr. at room temperature have complex crystal structures, involving d-spacings of the order of 11–12 Å. It is quite probable that many phases may be present under these non-equilibrium conditions. However, at this stage of decomposition, the equilibrium phases are definitely not present.

Since the synthesis and investigation of these amorphous foils are highly uncertain under the present experimental conditions, refinement of the apparatus so as to permit operation at liquid-nitrogen temperatures is now under way. Among the various facets of such non-crystalline metals and alloys which might be of interest, possible superconducting properties should be considered—especially since Buckel[1] has observed that certain metals in thin evaporated layers (amorphous structure) become superconducting at somewhat higher temperatures than with the normal crystal structures.

This work was jointly supported by the Office of Naval Research and the U.S. Atomic Energy Commission.

CHEMISTRY

New Compounds for the Control of Water Evaporation

CONSIDERABLE attention has lately been directed towards effective suppression of water evaporation from lakes and reservoirs by spreading insoluble monomolecular films over the water surfaces[1,2]. In order to be effective, the film-forming compound should have several desirable properties[3] such as: (i) low melting point (~50° C.), which will enable it to spread rapidly on the water surface so that its monomolecular film, if damaged, is easily healed; (ii) large equilibrium film pressure at the temperatures of water surfaces (15–40° C.) normally met with in practice; (iii) the film formed should be stable, incompressible and condensed.

Cetyl alcohol exhibits most of the above properties to a fair extent and therefore has been used as such or mixed with stearyl alcohol[4] in field experiments. However, laboratory experiments indicate that at 15–20° C. cetyl alcohol shows a reduction of evaporation of about 60–65 per cent, and at 30–35° C. the resistance is much lower (30–40 per cent) (Fig. 1). In field experiments such films show even lower resistance and are also not durable, since their resistance has been found to decrease rapidly in the course of 24 hr. or so. The influence of ambient temperature on the efficiency of cetyl alcohol film has been considered by Ramdas[5] and by others[1].

The higher homologues of cetyl alcohol should be more efficient but for their higher melting points. Substitution of the —OH group by a less active polar group no doubt gives rise to compounds with lower melting points, but the films formed by them are generally compressible[1,6] and give poor performance.

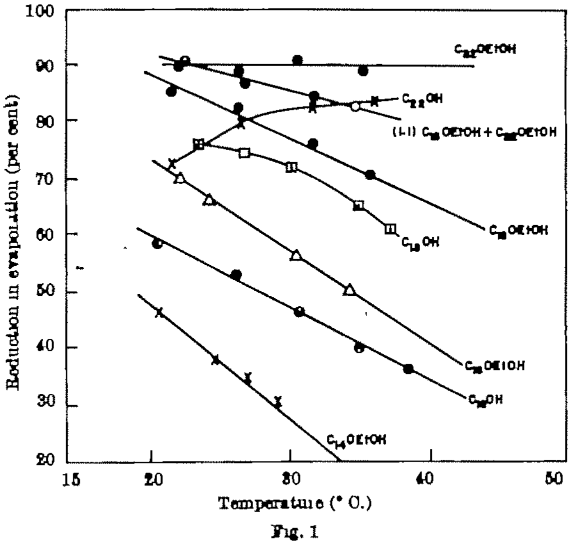

Fig. 1

Further, the films formed by most of these compounds deteriorate rapidly due to decomposition, hydrolysis or reactions with the impurities present in the underlying water.

The unsaturated alcohols have lower melting points, but in these, apart from their higher instability, the *cis*-alcohol (for example, oleyl alcohol, melting point ~5° C.) has a 'bent-chain' structure[6] and thus gives rise to non-compactness. The *trans*-alcohol (for example, elaidyl alcohol, melting point 36–37° C.) also does not yield an efficient film. On the other hand, it was considered that the introduction of an additional oxygen atom at the polar end of the saturated compounds would disturb the periodicity of the chain a little and the melting point would also be lowered slightly. Such a modification in the carbon chain would thus permit the use of longer-chain compounds.

A series of compounds $CH_3(CH_2CH_2)_n$—OCH_2CH_2—OH (referred to as *R*—OEtOH) were, therefore, prepared by reaction of the bromides of pure myristyl, cetyl, stearyl and behenyl alcohols with mono-sodium glycolate and purified by fractional distillation and crystallization. Experiments are also in progress to prepare similar products [*R*—$(OCH_2)_n$—OH] by the direct condensation of *R*—OH with ethylene oxide. A study of these compounds will, *inter alia*, allow us to determine the maximum number of molecules of ethylene oxide to be attached to an alkyl chain in order to obtain the most efficacious film-forming product.

To test the efficacy of retarders of water evaporation in the laboratory, 0·32 ml. of 0·09 per cent solutions of these compounds in 'Analar' (60–80) petroleum ether was spread over a clean water surface in a 9-cm. diameter Petri dish which, with a control dish, was kept on thermostatted metal bases and exposed for an hour to a breeze of 1–1·5 m.p.h. The films of pure cetyl, stearyl and behenyl alcohols were also tested under similar conditions. The reduction of percentage evaporation was calculated from the loss of water in the two dishes, and the results are plotted against the temperature (Fig. 1).

It was found that, for the normal alcohols, the reduction in water evaporation increases with the chain-length in the temperature-range studied, and the efficacy of the C_{14}- to C_{18}-alcohols increases steadily with the decrease in temperature. However, at lower temperatures, for the C_{18}-alcohol the curve tends to flatten whereas that for C_{22}-alcohol shows a decrease in evaporation resistance. This behaviour of the C_{18}- and C_{22}-compounds may be attributed to the difficulty of their spreading at low temperatures.

That the higher homologues of similar compounds with lower melting points show less difficulty in spreading is also borne out by the corresponding curves (Fig. 1) for the *R*—OEtOH products. In these, although the reduction of evaporation changes generally in the same way as that for the alcohols, it is greater and more persistent and there is scarcely any flattening of the curve except for C_{22}-OEtOH, which is surprisingly flat over the range of temperatures studied, indicating that the efficacy remains nearly the same throughout. An equimolar mixture of C_{18}-OEtOH and C_{22}-OEtOH shows reduction of evaporation intermediate between that of the two, as is also observed for similar alcohol mixtures. However, the efficacy of this film tends to be better than that of either component alone at lower temperatures, indicating the relative ease of spreading of, and formation of more compact film by, such a mixture as compared to that of the components.

Similar results were obtained on evaporimeter pans of 4 and 8 ft. diameter kept in an open field during different seasons and varying wind velocities (3–12 m.p.h.). Here also C_{16}-OEtOH and C_{22}-OEtOH consistently gave better reduction of evaporation than cetyl alcohol by at least 30 per cent in summer as well as in winter, and this was corroborated by laboratory experiments at various temperatures. The *R*—OEtOH films were also much more durable than the *R*—OH films, in that the effect of the former lasted for a period of about seven days in contrast to a day or so of the alcohols.

It may therefore be concluded that: (i) the selection of compounds for optimum suppression of water evaporation should be made keeping in view among other conditions the ambient temperature-range; (ii) $R—OCH_2CH_2OH$ or $R—(OCH_2CH_2)_n—OH$ types of compounds are better evaporation retarders than either cetyl or stearyl alcohols; and (iii) the C_{16}-OEtOH in colder season (~ 10–20° C.) and either C_{22}-OEtOH or its mixture with the former, during the summer (~ 25–35° C.), should prove more suitable in practice.

The process for the preparation and use of the new compounds (glycol mono alkyl ethers) for water evaporation control are being patented[7]. The results of fundamental studies on the specific resistance to evaporation, two-dimensional viscosity, rate of spreading, compressibility, phase behaviour, etc., of these and related compounds and their mixtures will be reported elsewhere.

We acknowledge the help given by Dr. L. G. Shah in the synthesis of the various compounds.

Character of the Ligands in Dibenzene Chromium

There has been considerable discussion concerning the molecular symmetry of dibenzene chromium, $(C_6H_6)_2Cr$ (refs. 1 and 2). Theoretical considerations led Ruch[3] to the assumption of a three-fold symmetry of the benzene ligands in the complex, the rings probably being slightly puckered[4]. Fritz and Lüttke[5] stated that the infra-red absorption spectrum of $(C_6H_6)_2Cr$ was incompatible with six-fold symmetry and proposed molecular symmetry D_{3d}. Recently, however, the same investigators[6] changed their interpretation of the spectrum; they proposed symmetry D_{6h} both for the molecule $(C_6H_6)_2Cr$ and for the cation $(C_6H_6)_2Cr^+$; this conclusion was based on a study of the infra-red and Rāman spectra, mainly of $(C_6H_6)_2CrI$. Snyder[7] also proposed an assignment of the infra-red spectrum of solid dibenzene chromium based on molecular symmetry D_{6h}. Six-fold symmetry of the benzene ligands is also assumed by most other investigators in the field of arene metal compounds[8,9].

In view of the importance of dibenzene chromium as the parent compound of the class of arene metal complexes I have undertaken a refinement of the crystal structure of $(C_6H_6)_2Cr$. The outlines of the structure had already been determined by Weiss and Fischer[9]. These authors found the compound to be cubic with cell edge $a = 9 \cdot 67 \pm 0 \cdot 03$ Å. and four molecules per unit cell. The derived space group *Pa*3 immediately led to a centrosymmetric 'sandwich' structure of the molecule, the packing of the molecules being similar to that in solid carbon dioxide. Assuming molecular symmetry D_{6h}, they derived distances C—C of $1 \cdot 38 \pm 0 \cdot 05$ Å. and Cr—C of $2 \cdot 19 \pm 0 \cdot 10$ Å. by trial and error.

My refinement is based on three-dimensional X-ray diffraction data which were obtained by Dr. I. Lindqvist and Mr. R. D. Rosenstein at the Chemical Institute of the University of Uppsala, Sweden. The data comprise the visually estimated intensities of 177 independent reflexions, covering 3,560 points of the reciprocal lattice. Refinement of the structure, mainly by difference syntheses, was straightforward. Extinction difficulties, such as described in the comperable case of the refinement of ferrocene[10], were not encountered to an appreciable extent. At the present stage the disagreement factor *R* amounts to 0·063 and for further refinement the anisotropy of the temperature motion must be taken into account. As this may be rather time-consuming, we feel justified in reporting our preliminary results.

Space group *Pa*3 was confirmed by us, and the cube edge was determined to be 9·667 Å. The molecular symmetry of $(C_6H_6)_2Cr$, however, was found to be distinctly different from D_{6h}. In the C_6H_6 ligands C—C bonds of length 1·353 Å. alternate with bonds of 1·439 Å., molecular symmetry D_{3d} being imposed by the space group. Since the estimated standard deviation in the C—C bond distances is 0·014 Å., the difference between short and long bonds is highly significant; furthermore, it is far too large to be ascribed to intermolecular interaction. The rings are found to be planar within the limits of accuracy; the distances of the carbon atoms to the mean ring plane are 0·008 Å. with an e.s.d. of 0·007 Å. The bond angles C—C—C are 118·9° ± 1° and 121·0° ± 1°, the distances Cr—C 2·135 ± 0·010 Å. and 2·132 ± 0·010 Å. respectively, which is somewhat shorter than has been reported for chromium arene carbonyls[11]. The distance of Cr to the mean ring plane is 1·613 ± 0·007 Å.

In low-angle difference syntheses[12] the hydrogen atoms are clearly visible at the expected distances of the ring atoms. High-angle difference syntheses show the thermal motion to be anisotropic, corresponding to a libration of the rings about the three-fold axis, but certainly not to free or almost free rotation[13]. The root mean square angular amplitude of the libration is approximately 7°, slightly less than in benzene at −3° C. (ref. 14). This libration causes an apparent shortening of the C—C bond distances of the order of 0·010 Å. and of the Cr—C distances of 0·006 Å.; the bond angles and the planarity of the rings remain unchanged. As stated, the anisotropy of the thermal movement has not yet been taken into account in my structure refinement.

The corrected C—C distances in dibenzene chromium of 1·45 and 1·36 Å. are significantly different from the distance 1·397 Å. found in free benzene[15]. They correspond more closely to the distances found for pure single and pure double bonds between carbon atoms with sp^2 hybridization, which have average values of 1·46 and 1·34 Å. respectively[16]. This indicates that little or no delocalization of bonding electrons takes place within the ligands of $(C_6H_6)_2Cr$. The cation $(C_6H_6)_2Cr^+$, on the other hand, possesses one electron less than the neutral molecule; electron spin resonance measurements have shown the unpaired electron to be distributed over the whole ion[17]. This, in its turn, may lead to delocalization of the bonding electrons within the rings and hence to six-fold symmetry of the ion. The chemical implications of the above hypotheses will be described elsewhere.

I wish to thank Dr. I. Lindqvist and Mr. R. D. Rosenstein for giving me their X-ray diagrams and intensity estimations, to Dr. D. W. Smits for adapting his refinement programmes for the electronic computer *Zebra* to the case of cubic symmetry, and to Mr. H. Schurer for performing most of the calculations on the *Zebra*.

BIOCHEMISTRY

Amino-acid Sequence about the Reactive Serine of a Proteolytic Enzyme from *Bacillus subtilis*

AN increasing number of hydrolytic enzymes have been reported to be inhibited by di*iso*propylphosphorofluoridate. Where the resulting di*iso*propylphospho-enzyme has been investigated, the phosphate was isolated in the form of phospho-serine peptides and the amino-acid sequence about the reactive serine has been determined in several cases. Trypsin[1] chymotrypsin[2-4], elastase[5,6] and thrombin[7] have the sequence Gly.Asp.Ser.Gly., while horse liver ali esterase[8] and pseudocholinesterase[9] have Gly.Glu.Ser.-Ala.Gly. The proteolytic enzyme subtilisin was isolated from a strain of *B. subtilis* by Güntelberg and Ottesen[10] and they recorded its inhibition by di*iso*propylphosphorofluoridate, while Matsubara[11] obtained a phospho-peptide from strain N^1 but did not report any sequence. The present communication deals with an investigation of the enzyme from Novo Terapeutisk Laboratorium known as 'bacterial trypsin', which is similar to, but distinguishable from, the original subtilisin.

A sample was treated with di*iso*propylphosphorofluoridate labelled with phosphorus-32 at pH 7·4 and a partial acid hydrolysate was subjected to ionophoresis on Whatman No. 52 paper at pH 3·5 in parallel with similarly treated chymotrypsin and liver ali esterase (sample kindly provided by Dr. E. C. Webb). The radioautograph of the ionogram showed that serine phosphate occurred in all three; but the pattern of phospho-peptides from bacterial protease was entirely different from that obtained from either chymotrypsin[6] or liver ali esterase and therefore there must be a different sequence about the labelled site. Repetition of the hydrolysis of samples of di*iso*propylphospho-enzyme, under the same conditions, gave markedly different proportions of the bands within the pattern. The proportions were also affected by subsequent air oxidation and thioglycollic acid reduction, and some individual bands were found to be interconvertible by oxidation or reduction. This suggested that there was, near the labelled serine, an amino-acid which could undergo reversible air oxidation. It seemed probable that this was methionine, which can be readily oxidized to the sulphoxide[12]. The di*iso*propylphospho-enzyme was therefore oxidized with performic acid to convert any methionine into the stable sulphone, and a simplified, reproducible pattern was obtained on hydrolysis. This pattern, which is also obtained if the previous hydrolysates were oxidized with performic acid prior to ionophoresis, is shown in Fig. 1 together with those from di*iso*propylphospho-chymotrypsin and di*iso*propylphospho-liver ali esterase.

The interrelationships of these oxidized bands (numbered in diagram) were determined by study of their behaviour to partial acid hydrolysis and Edman degradation[6] and their chromatographic and electrophoretic mobilities. Additional information about the N-terminal residue was obtained by treating the

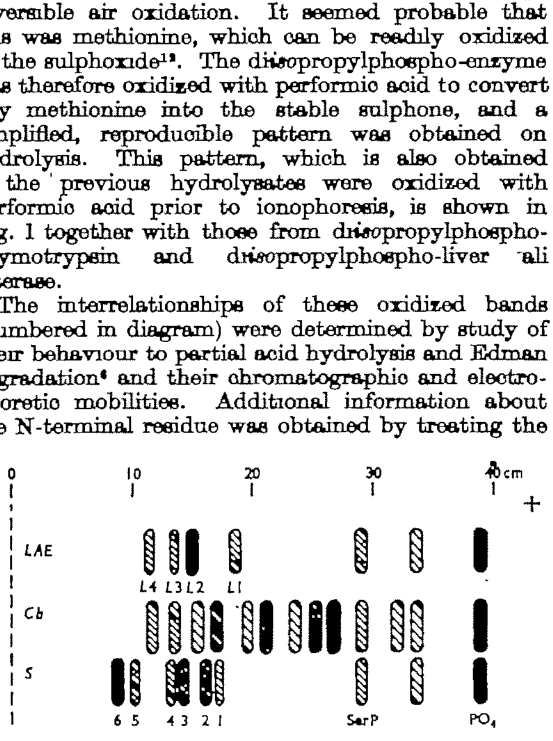

Fig. 1. Diagram of radioautograph of ionogram (pH 3·5, 40 V./cm., 2 hr.) of partial acid hydrolysis of di*iso*propylphospho-enzyme derivatives of liver ali esterase (*LAE*), chymotrypsin (*Ch*) and oxidized bacterial protease (*S*). The *LAE* bands are considered to be *L*1, Glu.SerP.; *L*2, SerP.Ala.; *L*3, Glu.SerP.-Ala; *L*4, Gly.Glu.SerP.Ala. The interpretation of the bands from chymotrypsin is being reported elsewhere (ref. 6)

Table 1

Peptide	Products of partial acid hydrolysis (excluding PO_4 and SerP)	Main radioactive product of Edman degradation	Effect of sodium periodate*
1	1	PO_4	–
2	2	SerP	+
3	1 and 2	1	+
5	1	PO_4	–
6	1, 2, 3 and 5	5	+

* + indicates that the peptide moved faster after treatment; – shows the peptide was not affected.

Peptide 4 is probably a larger peptide the structure of which has not yet been determined.

peptide with sodium periodate solution and observing whether the electrophoretic movement at *p*H 3·5 was affected. N-terminal serine and threonine residues should be oxidized to give a glyoxylic acid residue by loss of ammonia and formaldehyde or acetaldehyde, respectively[13]; so that the radioactive peptide would lose the terminal amino-group and should therefore move faster towards the anode. The results are summarized in Table 1.

A larger sample (50 mgm.) was then treated with di*iso*propylphosphorofluoridate labelled with phosphorus-32, oxidized with performic acid, hydrolysed and the radioactive peptides isolated by paper ionophoresis after removal of the neutral and basic peptides on a column of 'Dowex 50'. The amino-acid composition of each of these, after total hydrolysis, was determined on paper and is presented in Table 2.

Table 2

Peptide	Thr	Ser	Met SO_2	Ala	Asp	Glu	Gly
1	–	×××	××	–	××	*tr*	*tr*
2	×××	×××	–	–	*tr*	*tr*	*tr*
3	×××	×××	×××	–	×	×	×
5	*tr*	×××	××	×××	*tr*	*tr*	*tr*
6	×××	×××	×××	×××	*tr*	–	–

Relative amounts indicated by ×'s and obtained by visual comparison of intensities. *tr* indicates small contamination.

Contamination by non-radioactive, acidic peptides was not great and so from Table 2 and the determined interrelationships of the peptides, represented in Fig. 2, these experiments indicated the sequence Thr.Ser.Met.Ala.

It is interesting that the sequence about the reactive serine in this enzyme is totally different from those determined for other di*iso*propylphosphoenzymes. They had in common an acidic amino-acid, the serine and a small neutral aliphatic residue. Comparing subtilisin with chymotrypsin, trypsin, elastase and thrombin, which are all endo-peptidases with different specificities, it would appear that the sequence immediately about the serine is not responsible for the unusual reactivity towards di*iso*propylphosphorofluoridate which results in the inhibition of the proteolytic activity. Some other grouping, possibly including histidine[14], which is spatially close due to folding of the chain, probably activates the serine.

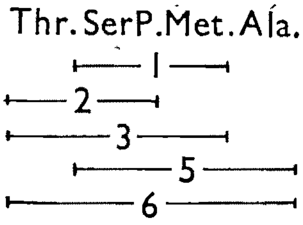

Fig. 2. Interrelationships of peptides. SerP indicates O-phosphoserine

PHYSIOLOGY

Effect of Testicular Hyaluronidase on the Permeability of Human Arterial Tissue

THE action of testicular hyaluronidase on acid mucopolysaccharides isolated from human aortic tissue was established in previous work from this laboratory[1]. The present investigation was undertaken with the purpose of studying the effect of testicular hyaluronidase on the permeability of arterial tissue membranes.

For determination of the tissue permeability, measurements were made of the diffusion coefficients of glucose for the membrane. The coefficient determinations were performed on three samples of the human aorta and three samples of the pulmonary artery, before and after the application of a solution of testicular hyaluronidase to the tissue, using the procedure of Johnson and Kirk[2]. After separation of the adventitia, intimamedia membrane samples of appropriate thickness were prepared. 50 ml. of a solution, consisting of 1 vol. 5 per cent glucose and 4 vol. Krebs's phosphate buffer, *p*H 7·1, were placed in the donor compartment of the diffusion apparatus, and 50 ml. of buffer solution in the recipient compartment. Two 1-hr. diffusion periods were first allowed to establish the permeability of the untreated membrane. Following this, the solutions were removed from the diffusion apparatus and the membrane and compartments rinsed with buffer solution. 5 ml. of a solution of testicular hyaluronidase (Alidase, Searle) in 0·05 *N* acetate buffer, *p*H 6·0 (30 viscosity units/ml.), were then introduced in both sides of the apparatus and were left in contact with the membrane for 2 hr. The membrane and the compartments were again rinsed with buffer solution, and glucose-buffer solution and buffer solution placed in the donor and recipient compartments. Diffusion coefficient measurements were then made in two 1-hr. periods. All experiments were carried out at 37° C. 30–45 min. were allowed to elapse

Table 1. Effect of Testicular Hyaluronidase on the Permeability of Human Arterial Tissue

Sample	Thickness of membrane (mm.)	Diffusion coefficient of glucose			
		Before hyaluronidase		After hyaluronidase	
		First period	Second period	First period	Second period
(1) Thoracic aorta	0·63	0·000082	0·000084	0·000103	0·000134
(2) Pulmonary artery	1·15	0·000065	0·000070	0·000091	0·000089
(3) Pulmonary artery	0·96	0·000138	0·000111	0·000297	0·000330
(4) Abdominal aorta	1·33	0·000063	0·000050	0·000074	0·000134
(5) Abdominal aorta	0·92	0·000078	0·000086	0·000086	0·000079
(6) Pulmonary artery	0·89	0·000039	0·000033	0·000041	0·000044
Mean		0·000078	0·000072	0·000115	0·000135

before each set of diffusion periods to permit penetration of glucose through the membrane.

The glucose analyses were performed in duplicate by the colorimetric method of Nelson[3], using the reagents described by Somogyi[4]. A Beckman *DU* spectrophotometer was employed for the colorimetric determinations.

The results of the experiments are presented in Table 1. It will be seen that a definite increase in the permeability of the arterial tissue to glucose was observed in four of the six experiments, whereas in two experiments no significant change was noted.

The diffusion coefficients observed for glucose for human arterial tissue in the present work before treatment with hyaluronidase are of the same order of magnitude as the values reported by Kirk and Laursen[5] for aortic tissue. The higher average values found in the second period following treatment with hyaluronidase may be due to a continued action of hyaluronidase in the tissue membrane.

Electro-shock Seizure Threshold of Metacorticoid Hypertensive Rats

It has been shown[1–5] that chronic administration of deoxycorticosterone acetate decreases brain excitability and potentiates anticonvulsant drugs, and that this effect is correlated with increased plasma and decreased brain intracellular sodium concentrations. In contrast, adrenal insufficiency produces the opposite effects[5]. Similarly, deoxycorticosterone acetate is known to be a relatively potent anæsthetic steroid[6].

Deoxycorticosterone acetate also produces, in the presence of dietary sodium, hypertensive cardiovascular disease and disturbances in mineral appetite. After the cessation of chronic administration of deoxycorticosterone acetate to rats, a metacorticoid state ensues in which these alterations persist[7,8]. It is felt that this hypertensive disease is mediated at least in part by increased arteriolar intracellular sodium[8,9]. It was of interest to determine whether the decreased brain excitability also persisted in metacorticoid rats.

Systolic blood pressures[10] and electro-shock seizure thresholds[11] were determined in 15 male Sprague–Dawley rats and in 30 similar rats that had previously received a subcutaneous implant of 20 mgm. deoxycorticosterone acetate and 1 per cent saline as drinking fluid for 3 months[8]. Both groups were being maintained on tap water, however, when blood pressure and electro-shock seizure thresholds were determined. The electro-shock seizure threshold refers to the convulsive threshold to a 60 counts per sec. current, delivered by corneal electrodes for 0·2 sec., that does not vary more than 1 m.amp. in 3 consecutive trials at least 48 hr. apart. The metacorticoid rats were found to have a mean electro-shock seizure threshold (35 m.amp.) that was not significantly different from that of the control rats (33 m.amp.), although their mean blood pressure (169 mm. mercury) was significantly elevated from control levels (129 mm.).

If the mechanism of electro-shock seizure threshold elevation by deoxycorticosterone acetate involves decreased brain intracellular sodium, and the mechanism of blood-pressure elevation by deoxycorticosterone acetate involve increased arteriolar intracellular sodium, then perhaps the former is reversible while the latter is not.

RADIOBIOLOGY

Delayed 'Primary' Effects in *Chara vulgaris* L. subjected to X-Rays

'Primary' or 'non-localized' effects in the form of clumping of metaphase chromosomes or the sticking together of sister chromatids in cells that complete mitosis shortly after irradiation during the period when mitotic frequency is decreasing have already been described by numerous investigators.

Study of the restoration process in the freshwater alga *Chara vulgaris* L. ($n = 14$) on X-radiation has shown that the effects referred to as primary could still occur long after irradiation, although re-establishment of the normal structure had already been achieved.

Irradiation was performed with unfiltered X-rays delivered by a Machlett *A.E.G.* 50 beryllium-window X-ray tube operated at 40 kV. peak and 25 m.amp. The dose-rate at the target distance employed (12 cm.) was 14,000 r./min., measured in air. The algae were irradiated under 5 mm. of tap water. The irradiation time ranged from 85 sec. (20,000 r.) to 28 min. (80,000 r.). After irradiation, the algae were put back in their normal culture conditions: filtered water from their place of origin, photo-period 16 hr., illumination 1,000 lux, temperature 20 ± 2° C.

In these conditions we observed for the most part that plants the telomes of which were treated with 20,000 r., 40,000 r. and 80,000 r., kept growing and formed whorls of phyloids having atypical morphology. Among these, however, a sudden restoration of the normal structure may occur after a series of 3–4 abnormal whorls. This process occurred about 5 weeks after irradiation. (A detailed study of the modalities of this process and survival and growth of irradiated algae will be published elsewhere.)

The mitosis of somatic cells in recovered whorls and of spermatogenous threads in antheridia borne by the former were investigated after fixing in modified Carnoy's fluid and staining with the Schiff reagent (Feulgen's method). This has shown a difference in the behaviour of nuclear divisions in these two cellular categories.

Whereas in the somatic cells the mitotic cycle is normal, without any appearance of chromosomic aberrations, on the contrary diverse mitotic disturbances were observed in the cells of the antheridial filaments. These differences are summarized in Table 1.

Table 1. MITOTIC ABERRATION FREQUENCIES IN SPERMATOGENOUS THREADS OF *Chara*

Mitotic aberration types per 100 cells	Dosage (kr)			
	0	20	40	80
Clumping (metaphase) (Fig. 1)	0	53·6	63·9	85·4
Stickiness (anaphase)	0	21·8	5·3	57·1
Anaphasic bridges	0	1·6	5·3	100
Micronuclei	0	5·8	0	4·8
Pycnosis	0	0	0	8·4

They are for the most part aberrations referred to as the usual 'primary', 'physiological' or 'non-localized' effects. The sister chromatid fusion results in bridge formation at anaphase.

The nuclei of the sperm mother cells resulting from these divisions also show different structural changes. With reference to Delay's work[1] on normal spermatogenesis in *Chara vulgaris*, the principal following abnormalities have occurred, especially in irradiated plants at 80,000 r.: (1) Central chromocentre ring, dumb-bell, filament shaped; (2) nuclear swelling or uneven contour of the nuclear membrane; (3) variation in nuclear volume; (4) nuclear fragmentation and pycnotic micronuclei.

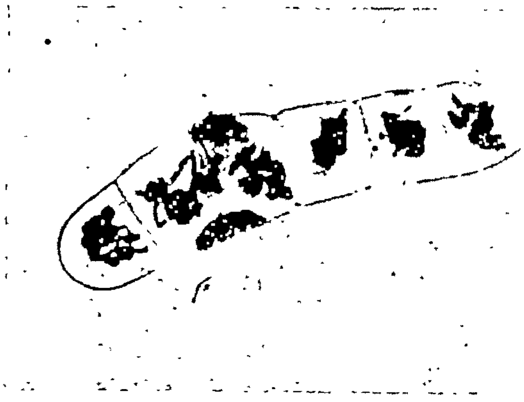

Fig. 1. Clumping in metaphase and stickiness in early anaphase. Spermatogenous thread of *Chara vulgaris* L. (× c. 1,500)

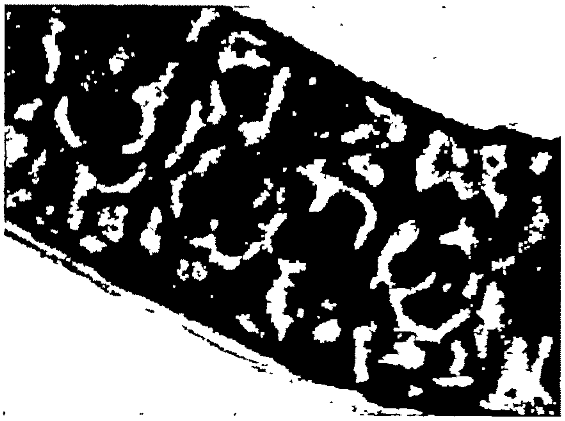

Fig. 2. Central vacuolization along the main axis (arrow) and degenerative pycnosis in the spermatozoids. Spermatogenous thread of *Chara vulgaris* L. (× 3,350)

Several degenerative processes occur in the spermatozoids: central vacuolization along the main axis and pycnosis (Fig. 2).

It is of interest to observe that aberrations referred to as primary effects can still appear at least 5 weeks following irradiation, after a minimum number of 12 mitoses between the irradiated apical cell and the antheridium initium, without the least mitotic damage being observed during the last nine divisions.

Thus it seems that these aberrations are bound with the metabolism of the nucleic acids in the course of spermatogenesis, whether this involves a depolymerization of deoxyribonucleic acid, as Darlington[2] and Taylor *et al.*[2] suggest, or partial dissociation of the nucleoproteins and damage to their organization pattern, as proposed by Kaufman[2].

These injuries due to X-rays are latent. The factor by means of which these injuries can be revealed is probably the very important heterochromatinization of the euchromocentric nuclei in the antheridial threads during spermiogenesis.

Moutschen and Dahmen[3] have stated that heterochromatin depolymerization and coalescence were emphasized by direct irradiation of the antheridia of *Chara vulgaris*. Moreover, some of the abnormal figures achieved by these authors immediately after direct irradiation are the same as those described here.

Effects referred to as primary are not limited to cells which complete mitosis immediately after irradiation; they can also occur in an organism long after X-ray treatment when the morphogenesis of the latter has again become normal. They can probably be transmitted by normal mitotic divisions and be revealed suddenly by a normal modification of nucleic acid metabolism in the nuclei heterochromatinization process during spermiogenesis in *Chara vulgaris*.

Fertility of Mice treated with Phosphorus-32

SINCE radioisotopes became available, many papers have been published concerning their clinical use as well as their potential harmful effects. One of these agents, phosphorus-32, is now occasionally being used in non-malignant conditions; consequently an effect which may be irrelevant in a cancer patient may become important in a young person who is likely to survive for some years; for example, the effect on the gonads. Previous knowledge on the subject is somewhat confusing[1-4], and no functional test has apparently been carried out so far.

The experiments reported here were carried out in *BALB* mice of both sexes, 1½–5 months old at the time of injection. Doses of phosphorus-32 ranging from 16 to 205 μc. were given intraperitoneally and the animals were mated with normal ones, previously checked for fertility, at periods of 1–8½ months after the administration of the agent. 3–12 months after treatment all the animals were killed and their ovaries and testes studied.

Tables 1 and 2 show the results obtained. 40 μc. seemed to be the threshold dose inducing sterility in all the females, since 6 of them so treated and mated with normal males revealed no pregnancy during 3–5 months of observation. With larger doses no pregnancies were encountered either, although the animals were kept under observation during periods up to 12 months. Males, however, were fertile even after receiving the largest dose administered, namely, 205 μc., which killed 5 out of 8 animals of this group. Since they were observed during periods ranging from 3 to 12 months, it seems safe to conclude that no dose short of the lethal one is capable of inducing sterility in males, whereas females become sterile with doses much below the lethal ones (approximately one-third *LD*50) and probably similar to those used in therapeutics.

Table 1. *BALB* FEMALE MICE TREATED WITH PHOSPHORUS-32

Dose (μc.)	No. of females treated	No. of females pregnant
16	2	2
28	8	3
34	5	4
40	6	—
60	2	—
90	6	—
120	8	—
200	3	—

Table 2. *BALB* MALE MICE TREATED WITH PHOSPHORUS-32

Dose (μc.)	No. of males treated	No. of males fertile
40·7	1	1
90	2	2
106	1	1
137	1	1
205	3	3

Ovaries and testes showed patterns generally in agreement with the observations of Bloom[1] and Odeblad[3]. However, no reappearance of the pearl formation in the ovaries, as described by Warren *et al.*[2], has been seen even 150 days after treatment. The results reported here seem to indicate that there is a real absence of oogenesis with doses of 40 μc. and not a decreased frequency as observed histologically by Warren *et al.* using much larger doses (250 and 2,000 μc.).

ANATOMY

Pattern of Hæmopoiesis in the Fœtal Liver

WHILE the importance of the hæmopoietic role of the fœtal liver is universally recognized, remarkably little precise information is available about the changing cytology of this organ during the course of development. The recent interest in techniques for the transfusion of suspensions of human fœtal liver, as a source of hæmopoietic stem-cells, has, however, made it desirable to study more fully the processes of fœtal blood formation.

We are investigating the development of the blood and blood-forming tissues in the human embryo and fœtus, using quantitative methods wherever possible. In 35 fœtuses, obtained by hysterotomy between the second and seventh months of pregnancy, the livers have been examined both in sections and in smears.

The composition of the hæmopoietic cell population of the liver differs in a striking fashion from that of the bone-marrow (Fig. 1), and it would appear that the pattern of hæmopoiesis in the two situations is fundamentally different. Whereas the cytology of the bone-marrow suggests active erythropoiesis and granulopoiesis from the inception of the hæmopoietic process, that of the liver indicates an overwhelmingly erythropoietic pattern of hæmopoiesis and we can find no evidence of granulopoiesis. The occasional granulocytes which are observed in liver preparations are in all probability derived mainly from the blood. Bridges *et al.*[1] administered a suspension of fœtal liver to a patient suffering from pancytopenia, and afterwards observed a pronounced granulocytosis. It is possible, therefore, that the liver does in fact contain myeloblasts, which *in situ* fail to differentiate into granulocytes because of local metabolic conditions but which do so on reaching an appropriate environment. The liver certainly contains a few cells which we would confidently label myeloblasts if we saw them in the bone-marrow.

The liver and bone-marrow also differ in their lymphocyte content. Although no evidence of lymphocytopoiesis can be found in even the earliest bone-marrow, about one quarter of its nucleated cells are

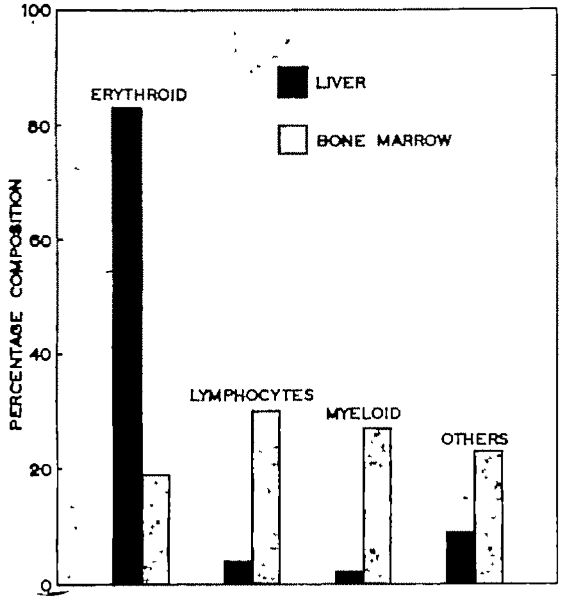

Fig. 1. Hæmopoietic cells of fœtal liver and bone marrow. Human fœtus, 203 mm. crown-rump length

lymphocytes; 15 per cent of these are transitional in appearance between typical small lymphocytes and hæmocytoblasts, resembling closely the cells previously described in the bone-marrow of the guinea pig by Yoffey[2]. In the liver, on the other hand, very few lymphocytes are seen and these, like the granulocytes in this situation, are probably derived from the blood.

The sparsity of lymphocytes in the fœtal liver, in which cell proliferation is extremely active, is difficult to reconcile with the view of Andreasen[3] and others, that lymphocytes are somehow mitotic adjuvants.

Furthermore, it seems unlikely that the lymphocytes of the bone marrow are concerned in antibody production, of which there is little evidence in early fœtal life. It would appear, therefore, that the lymphocyte population which is such a conspicuous feature of bone marrow—and presumably an indispensable cellular constituent from the earliest stages of development—must subserve a non-immunological function. The abundance of 'transitional' cells in fœtal marrow accords with the conclusion of Yoffey[4], that at least some of the small lymphocytes serve as hæmopoietic stem-cells in the marrow. Hæmopoiesis in the fœtal liver is quite unlike that in the bone marrow, for not only is it mainly erythropoietic, as has been noted already, but also the hæmopoietic stem-cell in this situation appears to be radically different from that in the marrow.

According to the widely accepted view of Maximow[5], it is represented by the undifferentiated mesenchymal cells which are trapped among the hepatic trabeculæ as they grow into the septum transversum. Our observations have failed to yield any evidence in support of this view. On the contrary, when mesenchyme occurs independently of hepatic trabeculæ, it contains very few differentiating hæmopoietic cells in comparison with the latter. Although occasional hæmocytoblasts and a variety of other immature hæmopoietic cells are seen intravascularly, in which situation they may undergo mitosis, the overwhelming majority of hæmocytoblasts and differentiating erythroid cells is extravascular, being found in the substance of the hepatic trabeculæ in intimate relationship with the liver cells. Here cells intermediate in appearance between hæmocytoblasts and early liver cells are observed in profusion and a complete morphological spectrum, linking the two, can be readily synthesized. We are, therefore, inclining more and more to the conclusion reached by Toldt and Zuckerkandl[6], that the hepatic hæmocytoblasts are derived not from the mesenchyme but from entoderm, namely, the as yet undifferentiated liver cells. In this connexion it is interesting to note that Gladstone and Hamilton[7] have ascribed an entodermal origin to the hæmocytoblasts of the human yolk-sac.

This work will be reported in detail elsewhere.

BIOLOGY

Recapture in the River Tweed of a Sea-trout marked in Devonshire

During the winter of 1959–60 a number of sea-trout (*Salmo trutta* L.) kelts were tagged at the experimental fish trap installed by the Ministry of Agriculture, Fisheries and Food in the River Axe at Colyford, south Devon.

One of these fish, tagged on October 29, 1959, was recaptured on July 21 (266 days after liberation) in the estuary of the River Tweed, Northumberland, at the Yardford fishery situated about four miles from the mouth of the river.

The minimum distance travelled from the point of tagging to the point of recapture, via the Straits of Dover, is approximately 580 miles and via the Irish Sea is approximately 1,130 miles.

In addition to this recapture, a number of other sea-trout kelts similarly tagged at the trap last winter have been recaptured in the Rivers Otter (1), Exe (1), Teign (4), Erme (1) and Taw (1). In the last case, the minimum distance travelled was 244 miles in 174 days. Two of the fish caught in the Teign were taken in fresh water several miles above the tideway but the others were taken in the estuaries of the various rivers. The extent of the migrations of sea-trout in the sea are almost entirely unknown and these observations suggest that they are more extensive than has hitherto been supposed.

Interspecific Hybrids of *Tilapia*: *T. nigra* × *T. zillii*

THE increasing recognition of fish (and in the tropics of *Tilapia* in particular) as farm animals has stimulated interest in the breeding of new and useful strains. In Malacca, Hickling[1] hybridized two geographical stocks of *Tilapia mossambica* Peters to produce both a faster growing strain as well as a skewed sex ratio in favour of males, the latter greatly simplifying the monosex culture technique of Brown and van Someren[2]. Hybrids have now been reported between *T. nilotica* (Linné) and *T. galilaea* (Artédi)[3], but their value for fish culture has not yet been assessed. Field observations led Lowe to suspect hybridization of the former with *T. nigra* (Günther) and *T. esculenta* Graham in Uganda[4].

The species involved in these crosses are female mouth-brooders. Although all show a basic similarity in breeding pattern, quite distinct from that of male mouth-brooders or substratum-spawners (as defined by Lowe[5]), interspecific differences, especially in courtship and male breeding coloration, have been considered important barriers to natural hybridization. It is therefore of great interest to record hybrids between the mouth-brooder *T. nigra* and the substratum-spawner *T. zillii* Gervais. It is difficult to imagine two more dissimilar species of *Tilapia*. They show striking differences, not only in breeding patterns but also in anatomy, behaviour and feeding habits.

Hybrids were found in a flooded rice paddy on the Tebere rice irrigation scheme in Kenya which had been stocked with *T. nigra*, but into which two male *T. zillii* had gained entry. Similar hybrids were also found in Lake Naivasha, Kenya, which had been stocked with both species. The hybrids were recognized in the field principally by coloration: dark body-shape the hybrids conformed to *T. nigra*; and the iridescent blue sheen of *T. zillii*; light, pearly green spots on the body and on dorsal, anal and caudal fins; no trace of the crimson flush on the chest found in breeding *T. zillii*, and no dorsal '*Tilapia*-mark'; and six or seven dark vertical bars on the body (absent in large *T. nigra*). In general body-shape the hybrids conformed to *T. nigra*; however, in all but one case the mouths were noticeably smaller. The Tebere hybrids also exhibited a 'gasping' behaviour (protrusion of the mouth) and tended to erect dorsal and anal fins when handled, a behaviour found in *T. zillii* but rare in *T. nigra*.

In most anatomical characters the hybrids resembled *T. nigra*, but (except in one case) larger specimens lacked the enlarged snout (elongation of the horizontal ramus of the premaxilla) associated with that species. Premaxilla, maxilla, dentary and articular were slightly shorter than in *T. nigra*, but less robust than those of *T. zillii*. Otherwise neurocranial, branchiocranial and pectoral elements, very different in the two species, were in the hybrids within the range of proportions found in *T. nigra*. Jaw and pharyngeal dentition resembled that of *T. nigra*, although simplification of the outer jaw teeth appeared to have been retarded slightly. Some hybrids had the three anal spines of *T. zillii*, while others had four anal spines (found in 10–20 per cent of natural populations of *T. nigra*). Five anal spines, the normal in *T. nigra*, occurred in 11 per cent of the Tebere hybrids.

Since female hybrids were not recognized in the field, but afterwards when post-mortem colour changes had eradicated the hybrid coloration, and since the few females found had either four or five anal spines, it is possible that female *T. nigra* were included in the samples. In most cases testes were well developed, and breeding occurred in ponds stocked with three- and four-spined males and five-spined females. No three-spined progeny were produced and the fry resembled *T. nigra* in all respects, including coloration. The cross male *T. zillii* × female *T. nigra* has been repeated at the Inland Fishery Research Station at Sagana in Kenya, and a brooding female was found after six weeks. The results of the reverse cross are not known.

Although the hybrids appear to be fertile, a skewed sex ratio may occur. Alternatively, spine-counts may facilitate the determination of the sex of small fishes. The production of a sterile or predominantly male weed-eating hybrid seems at present unlikely, only four hybrids having apparently fed on higher plants as does *T. zillii*.

These results will be reported more fully elsewhere.

Occurrence of *Pyrosoma* on the Continental Slope

Hurley and McKnight[1] have reported that the pelagic tunicate *Pyrosoma atlanticum atlanticum* rests on or swims just above the sea-floor at a depth of 160–170 metres. Indirect observations made on this species in the course of a line-fishing survey of the fishes of the south-eastern Australian continental slope[2] corroborate the concentration of this species near the sea-floor and extend the habitat to the floor of the continental slope.

While fishing off the east coast of Tasmania during June 1954–July 1955, 1,141 specimens of *Hyperoglyphe porosa* (Richardson) (deep-sea trevally)—previously considered to be quite rare—were taken by dropline in depths ranging from 330 to 640 m. These fish were found to feed almost exclusively upon *Pyrosoma*, their stomachs often being crammed full with the tests of this organism. Of 363 stomachs containing food 86 per cent contained the tests of large colonies of *Pyrosoma*. Fish having *Pyrosoma* in their stomachs were taken on hooks set 2–48 m. from the floor of the continental slope. Since fish were never taken until the fishing gear was touching bottom it is assumed that *Pyrosoma* were available at these depths. This would seem to be confirmed by the observations of Hurley and McKnight[1]. With one exception, all fishing operations were carried out during the hours of daylight, the incidence of *Pyrosoma* in the stomachs showing no significant variation throughout the day. Only 5 fish were taken at night and these had empty stomachs.

Thompson[3] recorded occurrences of *Pyrosoma* from Tasmanian waters at all seasons of the year and at all depths examined (0–500 m.) and was unable to discern any particular season of maximum occurrence.

From an examination of the stomach contents of *Hyperoglyphe* off the east coast of Tasmania in June, July, September and October 1954, and in January, March, May and July 1955, it was apparent that the incidence of *Pyrosoma* in the stomachs was at its maximum during the months of January and March. No other food organism became dominant at any time, so the incidence of *Pyrosoma* in the stomachs may reflect the seasonal abundance of the tunicate, though it could possibly reflect seasonal variation in the feeding intensity of the fish.

The specimens of *Pyrosoma* were identified by Mrs. M. Mather of the Zoology Department, University of Queensland.

MISCELLANY

'Dex' or 'Order of Magnitude' ?

THE phrase 'order of magnitude' is in constant use. It has at least two different meanings. In astronomy the magnitude of star *A* exceeds that of star *B* by unity if the amount of radiation (measured visually, photographically or bolometrically) reaching an observer or instrument on the Earth in a given time from *A* is $10^{-0 \cdot 4}$ or 0·3981 times that from *B*. In other sciences *A* is said to exceed *B* by an order of magnitude if it is ten times as large. To take an example, Lowy[1] wrote, "Thus, in the tonic anterior byssus retractor of *Mytilus*, the decay of tension can be two orders of magnitude slower than that of the active state". I take it that this means that the time needed for the tension to fall to a given fraction of its initial value after tonic contraction can be 100 times greater than the corresponding time after active contraction.

There is a shorter and more precise word to express such a comparison. This is the word 'dex', for 'decimal exponent', due to Allen[2,3]. He defines it as follows. "Dex converts the number before it into its 10-based antilogarithm. The term can be used for a typographically convenient method of expressing large numbers, as in the example 10^{39} = 39 dex. It can also be used to introduce verbal simplicity into statements on probable errors, ranges, and variations." He gives, among others, the example "The frequency range of useful radio-astronomy observations is 3·2 dex".

I suggest that outside astronomy 'dex' can always be substituted for 'order of magnitude' with advantage. I give a few examples from biology. "The range of weights of vertebrates is 10 dex, that of weights of birds only 4 dex." "A man consists of about 14 dex of cells." "The ratio of length to breadth in a nerve fibre can exceed 6 dex." "There are about 11 dex of birds." "The coefficient of variation of linear dimensions of unworn mammalian teeth rarely exceeds 0·05 dex." "The human ear has a frequency range of about 3·5 dex (1 octave = 0·301 dex) but the range of tones used in music is only 2·1 dex."

It can also be used with advantage in the social sciences, for example, "There are 8·6 dex of human beings in India, and about 8 dex of adult males. The range of incomes certainly exceeds 3 dex and may exceed 4".

Biologists will have to learn to think rapidly in terms of large numbers, as physicists, chemists, astronomers, and geologists do already; and even in the case of small numbers, the use of the word 'dex' may be an aid to precision of thought. I venture to hope that it may also be taken over from the terminology of astrophysics into other non-biological sciences. I am trying to use it systematically in lectures in this Institute.

PSYCHOLOGY

Effects of Medial Temporal Lesions on Taste Preference in the Monkey

MONKEYS with lesions in the medial portions of the anterior temporal lobes (the amygdala and pyriform cortex) tend to show marked changes in their responses to events that, pre-operatively, served as rewards or punishments. For example, it has been claimed that animals tend to be unafraid of snakes and strange people, to mount inanimate objects, to ingest a host of objects that were unacceptable pre-operatively. According to one descriptive generalization[1] monkeys are still motivated by reward and punishment, but the classes of events that are rewarding or punishing alter. In order to examine this view more specifically and also to rule out the possibility that the changes in reward–punishment classification occur simply because of changes in sensory capacity, the following experiments were undertaken.

Prior to operation saccharine preference curves for ten monkeys were determined. Each animal was given daily tests with one drinking dish containing distilled water and the other one containing saccharine sodium in one of four concentrations (1·0, 0·25, 0·05, 0·017 per cent). The actual concentration given on any day and the positions of the two dishes were randomized. Once a week both dishes contained distilled water.

This procedure lasted five weeks, so that a reasonably stable preference curve for each animal could be determined. Typically monkeys showed an aversion for the 1 per cent concentration and a moderate preference for the 0·017 per cent concentration, with a clear and strong preference for the middle two concentrations. Throughout the entire experiment, monkeys were provided with unlimited quantities of their standard diet of diet 41 lab chow, with vitamin C added.

In addition, with six of the monkeys, absolute thresholds for saccharine were determined using a method that does not depend upon the animal's preference for saccharine. The animal was trained to lick up 5 drops of a solution placed upon a piece of aluminium foil clamped to the top of a small iron cylinder. Until the animal made the licking response, the cylinder was held firmly in place by means of an activated electromagnet placed directly beneath it. If the solution was distilled water, the animal could then lift the cylinder within 10 sec. following the licking response and obtain a small piece of apple placed within it. If the solution was a saccharine solution, the animal was rewarded directly by the experimenter (who was situated behind a one-way vision screen) if he did not lift the cup for at least 10 sec. following the licking response. By systematically varying the concentration of saccharine, the point at which a weak concentration could no longer be discriminated from water was determined. The aluminium foil was renewed on each trial and an interval of 1 min. was inserted between all trials to allow for adaptation. An opaque screen was lowered between trials so that the animal could not see the solution being placed on the foil. The fact that thresholds were obtained indicates that the animals were not using extraneous cues in making their responses.

After these tests had been carried out, six of the monkeys were given bilateral medial temporal lesions, three were given partial striate cortex lesions, and one was given an anterior frontal lesion. All threshold and preference tests were then repeated, beginning one week post-operatively.

The results indicated that the absolute threshold for saccharine was not detectably altered in the six medial temporal monkeys. The average threshold was of the order of 0·008 per cent pre-operatively and post-operatively. Preference for saccharine, however, underwent a clear change in the medial temporal group as indicated in Figs. 1 and 2. The stronger concentrations became much more preferred than they had been pre-operatively. The weak concentrations did not change. In the striate control group, if there was any trend, it was in the opposite direction. (The data for frontal monkeys are not included in these graphs. As has been found in earlier studies, for example, ref. 2, they fell between the medial temporal and control group results.) Of the six medial temporal animals, all showed an increase in preference for the strongest solution; all three striate monkeys showed a slight decrease. Associated with the increase in preference for strong saccharine was, in some cases, a large increase in fluid intake for those solutions. One monkey, for example, consumed an average of 3,550 c.c. a day of the 0·25 per cent solution, which was almost equal to his own body-weight. On the weak concentrations, however, and on water versus water, there was no change in the total fluid intake, indicating that a simple diabetes insipidus will not account for the results.

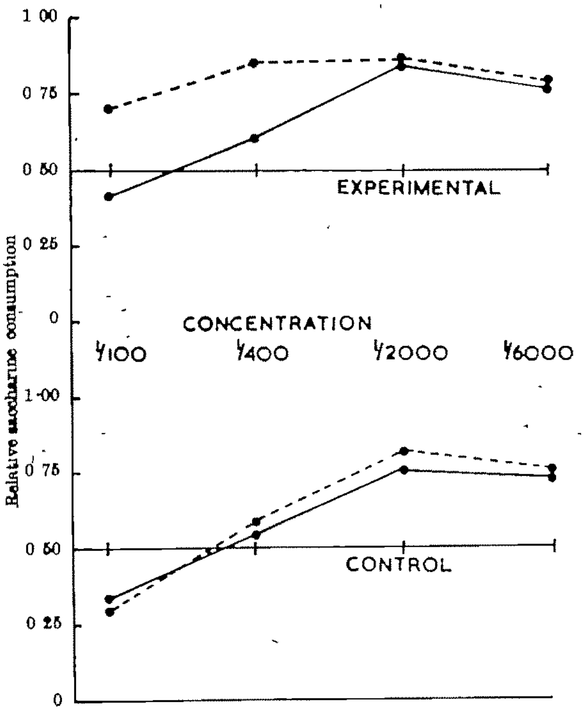

Fig. 1. Mean preference curves. The ordinate represents consumption of saccharine divided by saccharine plus distilled water. Each point is the average of all animals in each group, at least six determinations per animal with each concentration. ——, pre-operative; – – –, post-operative

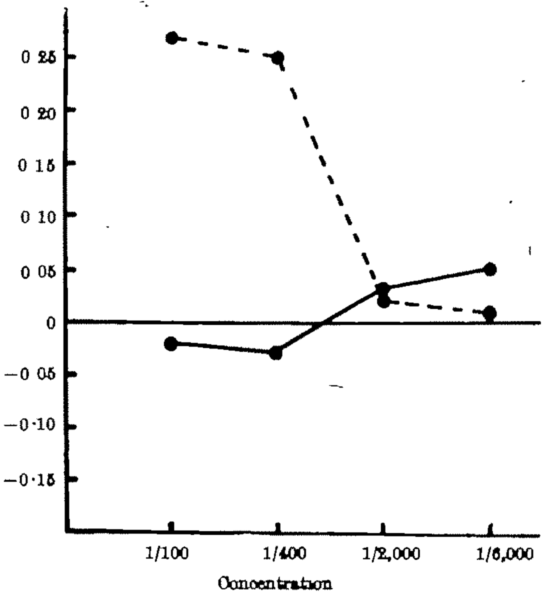

Fig. 2. Mean preference change. The ordinate represents the difference between post-operative and pre-operative preferences with each concentration, determined for each animal and then averaged. ——, Controls, – – –, experimentals

The results confirm, threfore, the view that medial temporal lesions change preferences—and thereby the relative strength of rewards—without changing the sensory capacity to discriminate the rewards. The experiments also incidentally point out the inadequacy of measuring changes in taste threshold in animals by means of preference, as is frequently done.

The preference results are unexpected in their direction. It was predicted, from gross observations, that the monkeys would become more indiscriminate, that is, tend to show no clear preference between saccharine and water. Instead, they became virtually saccharine 'addicts', especially for strong concentrations. Further work is therefore necessary to determine whether medial temporal monkeys prefer any strong testing substance or whether the change is specific to the dimension of sweetness. There is some evidence that the former alternative is likely.

FORTHCOMING EVENTS

Sunday, September 4—Wednesday, September 7

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Cardiff)—Continuation of 122nd Annual Meeting.

Sunday, September 4

At 11 a.m.—Service at Llandaff Cathedral. Preacher: The Bishop of Llandaff.

Monday, September 5

At 10 a.m.—Symposium on "World Food and Population". Chairmen: Sir George Thomson, F.R.S., and Sir James Gray, F.R.S. Principal Speakers: Dr. N. C. Wright, Prof. D. V. Glass, Prof. W. A. Lewis, Dr. L. Dudley Stamp, Sir Alexander Fleck, F.R.S., Dr. H. D. Kay, F.R.S., Prof. P. M. S. Blackett, F.R.S.

At 8 p.m.—Dr. E. B. Chain, F.R.S.: "Microbiological Methods in the Development of Drugs" (Evening Discourse).

Tuesday, September 6

At 10 a.m.—Mr. G. F. Mitchell: "Pleistocene History of the Irish Sea" (Presidential Address, Section C).

At 10 a.m.—Prof. D. V. Glass: "Population Growth, Fertility and Problems of Policy" (Presidential Address, Section N).

Wednesday, September 7

At 10 a.m.—Mr. Martin J. Wells: "What the Octopus Makes of it: Our World from Another Point of View" (Darwin Lecture).

Wednesday, September 7

INSTITUTE OF PETROLEUM (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. D. Downs, Mr. S. T. Griffiths and Mr. R. W. Wheeler: "The Part Played by the Preparational Stage in Determining Lead Anti-Knock Effectiveness".

POLAROGRAPHIC SOCIETY (at "The Feathers", Tudor Street, London, E.C.4), at 7 p.m.—Informal Discussion Meeting on "The Use of Ion Exchange Water in Polarography".

Thursday, September 8

PHYSICAL SOCIETY, ACOUSTICS GROUP (in the new Physics Building Imperial College, South Kensington, London, S.W.7), at 9.30 a.m.—Symposium on "Sound Propagation in the Atmosphere".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT IN VETERINARY PHARMACOLOGY in the University of Glasgow Veterinary Hospital—The Secretary of University Court, The University, Glasgow (September 9).

ASSISTANT INSPECTORS OF FISHERIES (2) (male, not over 40, with a degree, or equivalent in zoology, plus adequate knowledge of botany) IN THE DEPARTMENT OF LANDS, Dublin—The Secretary, Civil Service Commission, 45 Upper O'Connell Street, Dublin (September 9).

ASSISTANT EXPERIMENTAL OFFICER (with a degree in science or horticulture) IN THE ENTOMOLOGY SECTION—The Secretary, National Vegetable Research Station, Wellesbourne, Warwick (September 10).

BIOCHEMIST (Top grade) (well qualified chemist, preferably with a medical qualification) TO BE HEAD OF THE DEPARTMENT OF BIOCHEMISTRY—The Secretary, United Birmingham Hospitals, Queen Elizabeth Hospital, Birmingham 15 (September 10).

SENIOR LECTURERS (2) (preferably with a good honours degree and teaching or other suitable experience), one to teach electrical engineering and the other to teach electronics to equivalent degree level for Sandwich Diploma Courses—The Principal, Royal Radar Establishment College of Aeronautics, Malvern (September 10).

TECHNICIAN (preferably with experience in photography) IN THE DEPARTMENT OF ZOOLOGY—The Registrar, University College of Wales, Aberystwyth (September 10).

TUTORIAL STUDENT (graduate, or about to graduate) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, King's College (University of London), Strand, London, W.C.2 (September 10).

SENIOR LECTURER (with qualifications in either pure or applied mathematics) IN MATHEMATICS at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, September 16).

LECTURER (graduate with experience in the dairy industry or of dairy teaching) IN DAIRYING—The Registrar (Room 22, O.R.B.), The University, Reading (September 17).

RESEARCH FELLOWS (2) (preferably with a Ph.D. degree in engineering or physics, or equivalent research experience) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING (under Prof. A. L. Cullen), for work in the field of millimetre waves techniques—The Registrar, The University, Sheffield (September 17).

BRITISH OIL AND CAKE MILLS RESEARCH FELLOW (graduate, preferably with honours, in agriculture, economics or pure science) IN THE DEPARTMENT OF AGRICULTURE—The Professor of Agriculture, The University, Leeds 2 (September 21).

LECTURER/ASSISTANT LECTURER (with a good honours degree with suitable research and teaching experience, together with a good knowledge of both plant and animal biochemistry) TO TEACH AGRICULTURAL BIOCHEMISTRY at the University of Malaya, Kuala Lumpur—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Kuala Lumpur and London. September 30).

LECTURER IN CHEMICAL ENGINEERING at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, September 30).

PHYSICIST or SOIL PHYSICIST (Ref. SD.1) (with a first- or second-class honours degree in physics with at least two years postgraduate experience in research or in natural science with at least two years experience or training in soil science), for research on the mechanical and physical properties of agricultural soils and their relationship to the performance of tillage implements; and an ENGINEER (Ref. SD.2) (with a first- or second-class honours degree in mechanical or agricultural engineering or equivalent and with postgraduate experience in agriculture), for research on the design and performance of ploughs and cultivation machinery and on improved methods of cultivation—The Secretary, National Institute of Agricultural Engineering, Wrest Park, Silsoe, Bedfordshire, quoting appropriate Ref. No. (September 30).

SENIOR LECTURER IN FARM MANAGEMENT in the INSTITUTE OF AGRICULTURE, the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 30).

SENIOR LECTURER IN PREHISTORY IN THE DEPARTMENT OF ANTHROPOLOGY, University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, September 30).

SENIOR LECTURER and a LECTURER (with a degree in science or in agriculture, followed by postgraduate training in biochemistry, and previous experience in teaching or research) IN BIOCHEMISTRY at Canterbury Agricultural College, University of New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, October 15).

SENIOR LECTURER IN CYTOLOGY AND GENETICS at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, October 15).

SENIOR LECTURER or LECTURER IN PHYSICS at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, October 31).

UNIVERSITY LECTURER (with at least an honours degree in psychology and some knowledge of statistical methods) IN PSYCHOLOGY—The Secretary, Cambridge University Department of Education, 17 Brookside, Cambridge (November 3).

ASSISTANT PROFESSOR (Ph.D. or M.B.) IN PHARMACOLOGY—Prof. M. F. Murnaghan, University of Ottawa, Ottawa, Ontario, Canada.

ASSISTANT PROFESSOR OF PHARMACOLOGY—Prof. J. G. Aldous, Department of Pharmacology, Dalhousie University, Halifax, N.S., Canada.

ASSOCIATE PROFESSOR (preferably Ph.D.) OF HORTICULTURE at the University of Saskatchewan, Saskatoon, Saskatchewan, Canada—The Agent-General for Saskatchewan, 19 Chester Mews, London, S.W.1.

COMPUTER (preferably woman graduate) for the MATHEMATICS DEPARTMENT—The Assistant Secretary, University College, Gower Street, London, W.C.1.

COUNTY LABORATORY RESEARCH FELLOW, to work in the field of hair growth in collaboration with Dr. F. J. Ebling—Dr. F. J. Ebling, Department of Zoology, The University, Sheffield.

GEOLOGIST (man or woman, aged 23–45, with a degree in geology, general experience in geology and geophysics, and a knowledge of the occurrence of ground water) with the Government of Kenya, for the location of sites for water boring, geological mapping with special reference to the occurrence of ground water and general investigations connected with engineering problems—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.112/7/044/T.

HEAD (well qualified chemical engineer with responsible industrial experience, including that of original design, and preferably previous experience and/or research experience relevant to the development of undergraduate and postgraduate work in collaboration with industry) OF THE DEPARTMENT OF CHEMICAL ENGINEERING—The Registrar, Bradford Institute of Technology, Bradford 7.

LECTURER (with a good honours degree and teaching experience) IN THE SCIENCE DEPARTMENT, to teach pure and applied mathematics and statistics to G.C.E. Advanced Level and B.Sc. General degree students—The Clerk to the Governors, South-West Essex Technical College and School of Art, Forest Road, Walthamstow, London, E.17.

LECTURER or SENIOR LECTURER (with a university degree in medicine and preferably with interest in applied pharmacology and therapeutics) IN PHARMACOLOGY—The Secretary, Charing Cross Hospital Medical School, 62–65 Chandos Place, London, W.C.2.

PHYSIOLOGIST, Assistant Professor or Associate Professor (with an M.D. or a Ph.D. degree and capable of independent research)—Prof. M. Beznak, Department of Physiology, University of Ottawa, Ottawa, Canada.

POSTDOCTORAL FELLOWS IN THE DEPARTMENT OF CHEMISTRY, for research work in the fields of electron spin resonance spectroscopy of free radicals at liquid helium temperature, and mass spectrometry, including photo-ionization studies—Prof. C. A. McDowell, Department of Chemistry, University of British Columbia, Vancouver 8, B.C., Canada.

RESEARCH ASSISTANT for wind tunnel investigation in the field of industrial aerodynamics—Head of the Aeronautics Department, Imperial College of Science and Technology, South Kensington, London, S.W.7.

RESEARCH ASSISTANT (PHYSICIST) (preferably with a knowledge of electronics and a degree in physics), for work with the X-ray scanning microanalyser (electron probe) in the field of ore microscopy—Dr. A. P. Millman, Mining Geology Department, Royal School of Mines, Prince Consort Road, London, S.W.7.

RESEARCH ASSOCIATE IN CHEMISTRY, to work on the physical chemical properties and synthesis of heteropoly compounds—Prof. Egon Matijevic, Department of Chemistry, Clarkson College of Technology, Potsdam, New York, U.S.A.

TECHNICAL OFFICER (aged 22–25, with a degree in mathematics or an honours degree in geography with a mathematical background) IN THE SURVEY DEPARTMENT, Government of Kenya, for survey computations and checking of survey plans—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.103/7/09/Cl.

THE NEED FOR EDUCATIONAL RESEARCH

WHEN the first part of the Crowther Report was published in December 1959 it was recommended that more information about education should be obtained and made available : "... attention will have to be paid to the inadequacy of the tools that lie to the hand of the educational planner . . . There are the most extraordinary gaps in our knowledge of what goes on in the schools and technical colleges we have to-day . . . ". This is sharply brought out in Vol. 2 of the Crowther Committee's Report, which has now been issued*.

Before preparing its Report, the Committee was required to consider the work of technical colleges, the teenager in employment or industrial training, in the youth service and at leisure. The members always had to remember that two sexes were involved, each presenting its own educational and social problems ; and although little was known about the way educational and industrial and social pressures influenced boys, even less was known about their effects on girls.

What the Committee had not expected was that the factual evidence on which it could consider its terms of reference could be so meagre . . . "the information was sometimes lacking both to gauge the task or estimate the harvest. For instance, though an appreciable expansion in the output of students through the technical college courses was accepted as a major aim in public policy on which economic health on the long term depended, little was known nationally in 1956 about the circumstances in which students succeeded or, more often, failed, and how many years of study success or failure had cost them".

To help the Committee in its deliberations, special surveys were arranged with respect to the relation between home background and length of school life, of the progress of students through technical courses, the use of leisure, and the reserves of latent ability.

It is unfortunate that these three surveys could not have been published at the same time as the Report. They show both how slender was the evidence on which the Committee's sweeping recommendations were based and, more important, how much so-called educational progress is based upon popular—and sometimes passing—public opinion of a particular age.

In these surveys, for example, there is little or no evidence to support the Committee's major proposal to raise the school-leaving age for all children to sixteen. Accepting that "the attitude of the school-leavers themselves is obviously of importance in any examination of factors which may influence the length of school life", the investigators reported that "it was impossible to deal more than superficially with attitudes to the school-leaving age and reasons for leaving school". If any conclusion can be drawn from the survey report it is the rashness of the Crowther Committee in suggesting that *all* children should be kept in school until they are sixteen years of age. Thus, of the secondary modern boys and girls who had fairly recently left school and who were asked if they would have liked to stay longer, only 16 per cent of the boys and 23 per cent of the girls had regretted leaving school when they did.

A similar question was put to a group of National Servicemen, and despite their greater maturity and time for reflexion, only about one man in six who had left school at fifteen had afterwards wished that he had not left so early. Of those who had wished that they had remained in school longer, the investigators report that four-fifths of them realize that now, with better education, their chances of getting better jobs would be considerably improved. The investigators did not determine whether these young men of eighteen were seeking to remedy the defects in their education or whether they had the capacity to profit by it. Their wistful desire for more education may have been more bound up with the fruits of better jobs than with the effort required to attain them.

The Government's decision to make no firm forecasts about the date on which the school-leaving age is to be raised was largely based on financial and economic arguments. Before a great step of this nature is taken, it could well spend a little money to dig deep for information which has only been scratched in these surveys. Many well-informed people believe that it is educationally and morally wrong to compel all young adolescents to continue a formal education which many of them find irksome and restrictive, and which might well contribute less to their social and educational development than would a planned period of vocational training in industry supported by continued education of both a vocational and recreational nature.

If educational reformers are genuine in their desire to bring the greatest educational good to the greatest number, they should first accept that more than their own wishes and experience is needed before advocating a 'reform' which could well bring misery and frustration to many young people. Evidence has been accumulating that young people (and especially girls) of fifteen to-day are as mature as young people of sixteen and seventeen of 25 years ago. In terms of biological and psychological age, may not the 1944 goal of raising the school-leaving age to sixteen have already been reached ? More information about the wishes and feelings of young people is required.

For a number of years much has been made about the ill-effects of too much money on young wage-earners. Little real investigation has been carried out to determine the truth of this charge. The majority of young delinquents come from boys and girls still at school. Why ? Which types of schools—grammar, or modern, or comprehensive ? Also, from which classes in the school? *A* stream or *D* stream? Is there direct correlation between the delinquents and the types of homes from which they come? Doctors, youth leaders and industrial training officers could well join parents and teachers in providing much useful information about the needs of young adolescents. So, too, will the investigation being carried out by the University of Sheffield into transition between school and work. Before the precedent is set of compelling all young people to remain at school until they are sixteen—at present those who stay on at grammar, technical or modern school do so because they wish—much educational research is needed into the biological and psychological and social requirements of young people and how they can best be met.

---

* Report of the Central Advisory Council for Education—England. 2 (Surveys). (H.M. Stationery Office.) 8s. 6d.

The case for more research to support educational thinking is also brought out in the third survey conducted on behalf of the Crowther Committee. This was undertaken to establish the broad facts about the efficiency of education continued by part-time day release classes. For some years investigators whose contacts with industry have been superficial have raised considerable dust about the wastefulness of City and Guilds and National Certificate courses. Their standards were set almost entirely by the number of students who began courses and the numbers who obtained Final City and Guilds and Higher National Certificates. (See also the article by Dr. J. Heywood in *Nature* of July 16, p. 189.)

The survey now shows that since National Certificate courses were begun in 1923 some 18,028 Ordinary National Certificates have been awarded, about a third of these going to students who left school at the minimum statutory age. "Neither should the wastefulness of the process be exaggerated. The shedding has taken place pretty steadily along the route, and it is not a fact that all those who have not reached the end of the road have wasted many hundreds of hours of their own and their teacher's time in fruitless endeavour." Those who have regarded the process as utterly wasteful have insisted that more attention be paid to selection, and that teachers in technical institutions should join industrial management in making the selection of industrial apprentices and others. This report makes it clear that much more than stringent selection at the outset is required. "The course itself is a kind of selective process, and all that may be hoped of a more stringent and deliberate process is that it would be somewhat, but not a great deal more efficient."

This report will remind many educationists of the Education Act of 1944. Against the advice of almost every educational psychologist, a tripartite system of secondary education was set up with rigid selection at the age of eleven. Although administratively convenient, the folly of the tripartite system has become only too evident in the last fifteen years. It is to be hoped that future reforms will be based much more on facts patiently gathered by careful investigation rather than by well-meaning intentions to do good. It is time the social reformer was replaced by the social engineer, who uses facts as a basis for change.

DESIGNING FOR SPACE TRAVEL

Soviet Space Science

By Ari Shternfeld. Translated by the United States Air Force (Technical Documents Liaison Office). Pp. xxii+361. (London: Hutchinson and Co. (Publishers), Ltd., 1959.) 30*s*. net.

Space Technology

Edited by Prof. Howard S. Seifert. Pp. xvi+1160. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1959.) 180*s*. net.

PERHAPS the most dramatic engineering development of the past few years has been the demonstration of the practicability of flights in the solar system at least by unmanned vehicles. The development of this technique has received a substantial impetus from motives as diverse as a recognition of a new, powerful tool for astronomical observations and the desire for pre-eminence in human space-travel for political reasons. Space technology is in consequence rapidly building up a literature to which the two volumes forming the subject of this review represent substantial additions. Since ultimately they emanate one from each of the two nations most concerned with these developments it might be supposed that they would provide an interesting comparison, but a comparison is vitiated by the fact that they aim at quite different readers. Moreover, "Soviet Space Science" draws information from sources on a wide international basis showing, if anything, a bias towards American work in the field.

The title is, in fact, altogether a misnomer, for this book is really concerned with space flight. The first and largest section, comprising five chapters, deals with the launching and subsequent motion of an artificial Earth satellite. The explanation is clear, detailed and non-mathematical, and at times unduly repetitive. It is evidently aimed at a non-technical reader since extensive use is made of tables and diagrams rather than graphs. Subsequent chapters are concerned with the hazards and physiological problems of manned space flight, the scientific uses of satellites and space probes, the problems of telemetry and communication, and landing. In these sections the author is content to skim over the surface of his subject; it is noticeable that no effort is made here, unlike the opening chapters, to expound the basic principles. Moreover, few references are made to the direction of future technological advances, even where their direction can be clearly discovered.

Particular exception can be taken to the account of experimental space science, which is very shallow, and where the language employed is often imprecise. (For example, the expression "the voltage of the current" is used.) There is not a large number of misprints in the book, and it is unfortunate that they should largely occur among the numerics in this section, where they are particularly liable to mislead.

There are two appendixes, dealing respectively with astronautical societies and the international law of space, an epilogue by Willy Ley, which brings the account of vehicles launched up to *Lunik* I and a good index.

"Space Technology", which deals primarily with the engineering of guided rockets for orbital missions, is based on a series of lectures delivered during 1958 at the University of California by a total of 38 different lecturers. The editor, Prof. Howard S. Seifert, has handled with considerable success the problem of reducing to a reasonably uniform style and level contributions from such a large number of authors.

The book opens with a brief introduction of a historical and astronomical character, which is followed by an extensive account of the motion of powered and unpowered vehicles in gravitational fields. Approximate methods of calculation, such as perturbation techniques, are described for the many-body problems which are encountered, leading to the solution of design optimization problems. The topics covered in this way include ballistic missile trajectories, Earth satellite orbits and lunar and interplanetary flights (in which propulsion is used only near the beginning and end of the flight). These are followed by an account of the use of low-thrust motors, such as those employing positive-ion jet or nuclear fuels, to expand Earth satellite orbits for interplanetary travel. After a chapter on relativistic time dilatation effects, this section concludes with a description of methods of soft landing. It will be seen that this part of the book is both detailed and comprehensive. The explanation of some of the most complex orbital problems, such as the motion of a satellite in the Earth–Moon system, is excellent and brings out very clearly the principles involved. Similarly the limitations of various propulsion systems for different missions are thoroughly covered.

The subsequent sections are somewhat less detailed and deal with propulsion (using both chemical and nuclear fuels), rocket system design procedures, communications, guidance, and the physiological aspects of manned flight. The last section is rather briefly concerned with the upper atmosphere and the scientific uses of satellites. Finally, there is, even for the enthusiastic reader, an examination paper of 102 questions!

In conclusion, it can be said that "Space Technology" gives an excellent account of the methods employed to select optimum orbits. The description of motors and guidance systems provides a good background to this subject and an introduction to its technological aspects. A certain amount of information on the environment which will be encountered, in planetary atmospheres, for example, and on the performance which can be expected from human beings in a space ship, is also presented. Most of this is rather general in character, and these sections suffer from a rather low density of hard facts.

In perspective, both the books which are the subject of this review can be seen as descriptions, at quite different levels, of the dynamics of space vehicles together with an account which is given in breadth rather than depth of the associated technology and planetary physics. Each in its way can be recommended.

A SOURCE-BOOK OF SEMICONDUCTOR PHYSICS

Semiconductors

By Dr. R. A. Smith. Pp. xvii+494. (Cambridge: At the University Press, 1959.) 65*s*. net.

SEMICONDUCTOR physics has become a vast field of research and development over the past decade. Any text on the subject must of necessity be selective, but in the present volume the author has presented those topics which are of fundamental interest and moreover has provided critical discussion at all stages. This is particularly important for those who may use the book as an introduction to the theoretical aspects of phenomena with which they are concerned experimentally. It is perhaps not often realized that a semiconductor cannot always be distinguished by a negative temperature coefficient of resistance, as is pointed out in the first chapter. Here can be found a reference to other problems of early work in the field which were only resolved by the production of single crystal specimens of high purity, by the careful distinction between volume and surface effect on physical properties, and by recognition of the decisive part played by crystal defects and impurities. In introducing the essential wave-mechanical basis of semiconductor physics, Dr. Smith is careful to carry the reader forward to more complex configurations than simple spherical energy-surfaces in wave vector-space, and to indicate the important experimental approach obtained in cyclotron resonance. In treating crystal binding some brevity has obviously been necessary, but one cannot help wishing that the problem of mixed binding and experimental methods of assessment had been afforded more discussion. In reading the section on excitons the reader must not forget that in the case of some high-band-gap materials, such as cadmium sulphide, the existence of excitons is not satisfactorily proved.

Many of the phenomena associated with semiconductors occur under conditions of thermal equilibrium or with very small departures from it. It is not therefore surprising that a significant fraction of the text is devoted to energy distributions of electron and positive holes, to transport phenomena and to the very important matter of scattering mechanisms for carriers. This part of the book is very up to date; for example, a discussion of recent work on 'hot' electrons, that is to say, carrier behaviour in high electric fields, is included. There is also a very adequate treatment of thermomagnetic effects not always found in texts on solid-state physics.

Much information on semiconductors results from a study of optical properties such as the position and structure of the lattice absorption edge. The author gives a review of recent experiments and their significance in distinguishing between direct and indirect, phonon-assisted, electron transitions. Here he draws on powerful data obtained by his own research team, among others. Within the electro-optical phenomena discussed none is perhaps more important than the release of carriers by photon absorption, which manifests itself in photoconductivity, the photovoltaic effect and the photo-electromagnetic effect. These are described briefly at first, but elaborated later in the book when a treatment of carrier diffusion has been given which provides a more complete and essential background for discussion. In the latter section we find the *p*-*n* junction, the problems of contact and surface conditions and the mechanisms of carrier injection and recombination.

For many experimentalists it will be a pleasure to find that after many pages of theoretical treatment Dr. Smith anchors it all by a critical review of the experimental methods available for the determination of the many parameters which have previously emerged in the theory. His chapter on such methods effectively introduces the survey of practical semiconductors of various types, particularly germanium, silicon, intermetallic compounds and, from his particular interests in the past, the sulphide, selenide and telluride of lead. The latter is a useful inclusion, although a more complete account has been given previously by the author and some of his co-workers. High-band-gap semiconductors may appear to have been neglected, but data for them are so incomplete and still inconclusive compared with those for such solids as germanium and silicon.

This book makes an important and critical contribution to the subject which is based on the author's personal experience as leader of one of the most important research teams of to-day in semiconductor physics. It will be an excellent 'source-book' for many workers in this and closely related fields, and will certainly satisfy an important need in postgraduate university courses of solid state physics.

G. F. J. GARLICK

SOLID STATE PHYSICS

Solid State Physics

Advances in Research and Applications.
Vol. 7. Pp. xiv+525; 1958. 12 dollars.
Vol. 8. Pp. xiv+519; 1959. 13.50 dollars.
Vol. 9. Pp. xv+548; 1959. 14.50 dollars.
Vol. 10. Pp. xv+516; 1960. 14.50 dollars. Series edited by Frederick Seitz and David Turnbull. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd.)

Paramagnetic Resonance in Solids

By William Low. (Solid State Physics: Advances in Research and Applications, Supplement 2.) Pp. viii+212. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 7.50 dollars.

THE contributions to the volumes of "Solid State Physics" under review maintain the high standards of scholarship and readability set by previous writers in the series. Research workers in the field have come to rely so much on "Solid State Physics", both as an invaluable source for their own work and as a kind of lifebuoy to keep them afloat in the flood waters of the literature, that one wonders how the subject maintained any kind of unity before the series was started. Perhaps it did not; and perhaps even now individuals read only articles bearing directly on their tenth (or hundredth) of the field. If this is so, the best service a reviewer can do is indicate the nature of the topics discussed.

There are three major articles on electrons in metals. J. Callaway, in "Electron Energy Bands in Solids" (Volume 7), describes first the general properties of bands (with special reference to symmetry and the use of critical points) and then gives a complete survey of existing experimental and theoretical results. It is all very carefully done and it is apparent that the calculations are now sufficiently sound for experiments to constitute a genuine test of theoretical assumptions about core potentials. The oscillatory dependence of magnetic susceptibility and electrical conductivity on the magnetic field is considered by A. H. Kahn and H. P. R. Frederikse in Volume 9. These phenomena are now very effective tools for investigating electron bands—especially the shape of the Fermi surface. There is a fine, 200-page article by the late M. R. Schafroth on superconductivity in Volume 10. Half the article is phenomenological and half is microscopic; it constitutes the best available account of the exciting progress in this field since 1950. The author's exposition of Bogoliubov's version of the theory is specially lucid and convincing. In spite of the present inability to explain the vanishing resistance (which gives the phenomenon its name) and the still controversial explanation of the Meissner effect, the other phenomena are now so well explained that one must surely accept Schafroth's conclusion: we are very close to a final theory of superconductivity.

The next group of articles is concerned with lattice properties of solids. A. F. Wells, with characteristic clarity and excellent illustrations, describes and classifies inorganic crystal structures in Volume 7. This is done not from the formal basis of symmetry, but rather from a more friendly and intuitive 'topological' point of view which asks how crystals can be built up from given elementary units of bonds and nets. Also in Volume 7 is a long and useful review by H. B. Huntington giving theory, experimental methods and results concerning the elastic constants of crystals. Among many other topics, the author discusses Laval's question: "Should local rotations and torques be considered in forming the elastic tensor?" The verdict is 'not proven'. D. Lazarus in Volume 10 gives a full and satisfying account of diffusion in metals. In Volume 7, P. G. Klemens contributes an article on the difficult subject of lattice thermal conductivity. An attractive feature of the paper is the way in which the author describes how the measurement of thermal conductivity can be used, at least as a supporting technique, in the study of crystal defects: dislocations, stacking faults and grain boundaries.

Defects and inhomogeneities in crystals are discussed in three further papers. There is a long article on the structure and properties of grain boundaries by S. Amelinckx and W. Dekeyser in Volume 8. This succeeds well in tying together the modern theoretical work which treats grain boundaries as arrays of dislocations and the extensive experimental findings, structural and kinetic. Certain aspects of the continuum theory of stationary dislocations are developed further by R. de Wit in Volume 10 than they were taken by Eshelby in an earlier volume of "Solid State Physics". In curious contrast to the state of affairs 100 years ago, it seems that one now discusses elasticity with the help of electromagnetism. A. Guinier writes in Volume 9 on "Heterogeneities in Solid Solution". The article naturally deals with the Guinier–Preston precipitation-zones in aluminium–copper alloys, but includes much more, such as a section on short-range order in solid solutions in equilibrium.

The editorial policy of providing detailed surveys of important groups of semiconductors is continued here with three contributions. W. W. Scanlon writes in Volume 9 on a little-known group of polar semiconductors: lead sulphide, lead selenide and lead telluride. The important feature of these materials is that whereas they enjoy NaCl-type binding and structure, their energy gap is sufficiently small to allow the electrical properties to be investigated easily. They thus form more useful test materials for the theorist than alkali halides. A detailed account of electronic processes in zinc oxide is provided by G. Heiland, E. Mollwo and F. Stöckmann in Volume 8, and in the same volume R. Newman and W. W. Tyler review photoconductivity in germanium. The latter authors emphasize the usefulness of germanium—the intrinsic properties and impurity levels of which are well understood—as a model for theories of photoconductivity. Consequently their article is much more than a collection of results.

In Volume 10, B. S. Gourary and F. J. Adrian present an elaborate account of the work on wave functions for electron-excess colour centres in alkali halides. This is one of four articles on the optical spectroscopy of solids. Two of them are on the relatively new field of molecular spectroscopy in molecular crystals (for example, benzene, anthracene) and cover virtually the same ground. I found the article by H. C. Wolf in Volume 9 more coherent and enlightening and indeed more up to date than the article on the same topic by D. S. McLure (Volume 8). However, the latter author has provided us with an excellent account of the spectra of ions in crystals (Volume 9), where, of course, the symmetry properties of crystalline fields are of vital importance.

The articles mentioned above contribute to well-established branches of solid state physics. Rather more exciting to the novelty seeker are a group of three reviews describing applications of the techniques of nuclear physics to problems of the solid state. Perhaps the best known of these topics is the use of thermal neutrons to investigate vibrational spectra, discussed in workman-like manner by L. S. Kothari and K. S. Singwi (Volume 8). More esoteric is the use of angular correlation measurements on oriented nuclei to get extra-nuclear data, examined by E. Heer and T. B. Novey in Volume 9. The idea is that in the time between successive nuclear emissions, local nuclear motion may perturb the intermediate nucleus. The information obtained is similar to that found by studying spin-lattice interactions by nuclear magnetic resonance. Although the technique is clearly far less flexible and general than that of nuclear magnetic resonance, it may be useful in some cases because, first, no radio-frequency field is needed and, secondly, it can be made to work with about 10^{8} nuclei cm.$^{-3}$ as compared with the nuclear magnetic resonance requirement of 10^{18} nuclei cm.$^{-3}$. Perhaps the main lesson to be learnt from D. R. Wallace's account of position annihilation in solids and liquids (Volume 10) is that this phenomenon is less a tool than a challenging problem in its own right—one that is far from exhausted.

New results on surfaces are expounded by J. A. Becker in Volume 7. They have been obtained by the ingenious use of ion gauges and field emission microscopy. It is remarkable that Müller's recent extension of the latter technique, in which ions are used instead of electrons to form the image, permits surface pictures which, at least in some respects, show the surface on an atomic scale.

I was specially attracted by a delightful article by D. J. Montgomery (Volume 9) on one of the oldest, yet least understood, topics in physics: the static electrification of solids. While concealing none of the essential complexity of the problem the author has been bold enough to describe a simple rational scheme based on electron transfer from the bulk of the solid (thereby ignoring specific surface effects) which seems to give a 'zero order' account of the main phenomena. Teachers who dabble in the catkin and amber branch of witchcraft will read this article with pleasure and profit.

In addition to the main volumes described above, there is a second 'supplement' consisting of a monograph on paramagnetic resonance in solids by W. Low. Although most of the material can be found in three well-known reviews published elsewhere, this is the first connected account of the whole subject since the early 1950's. It is admirably done, and will clearly become a theoretical handbook for workers in the field.

R. O. DAVIES

CHEMICAL ENGINEERING PRACTICE

Chemical Engineering Practice

Edited by Herbert W. Cremer and Sidney B. Watkins. Vol. 11: Works Design, etc. Pp. vi+390+xviii. (London: Butterworths Scientific Publications; New York: Academic Press, Inc., 1959.) 95s.; 13·30 dollars.

CHEMICAL works are frequently large in area, and in their general design and administration present problems which are to be found in all large enterprises. In this volume we are taken away from the specialized field of chemical plant design and are concerned with the more general topic of works construction and organization; we are concerned with the factory and its problems rather than with the details of any particular unit.

This is a guide to the structure of a large chemical works. We are brought face to face with the problems of management of people, of the arrangement of contracts, and with planning and production and its impact on sales. The peculiarities of the chemical industry, with its frequent demand for continuous working and the resulting problems for personnel, its hazards arising from the toxic and inflammable nature of many of its materials and processes—all these difficulties are clearly indicated as part of the life of a chemical works. In the very long section on works administration Mr. Hiscock of the Consolidated Zinc Corporation, Ltd., gives some suggestions for their solution. Those entering these industries are usually crammed with academic facts, but here they can see that they will be brought problems which will demand an entirely new approach. It is not simply a question of learning the techniques of a given industry, it is a question of harmonizing the demands of a very wide range of people to form a happy community. There must be an understanding of what constitutes incentive. "Work study does not replace management, nor does it necessarily ease the burden of management". "Method study presents facts; it does not make the decision. Whether to proceed is the responsibility of management". The importance and problems of work study in the chemical industry are in general agreed; but it is very useful to have the facts set out, and their limitations, as in this text.

The chemical industry in Britain, like other enterprises, is governed by Factory Acts and other legislation. Many in all positions in the chemical industry will be indebted to Sir George Barnett for his most welcome chapter on "Factory Acts and Legislation". This chapter, together with that by Dr. Carter on "The Alkali Acts and Works Regulations", should be read by all who contemplate entering this industry. We can see from this text the kind of organization that must be developed if the problems of the chemical industry are to be tackled and inducements given for profitable working in the company. This is above all a record of experience, of personal observation and analysis. We can learn from here something of the secret of 'what makes a factory tick'. We can learn from a body of men who have all taken an active part in developing industries of this kind. This is an excellent volume for which we should be grateful to Mr. Cremer and Mr. Watkins.

J. M. COULSON

SCIENCE AND MEAT

The Science of Meat and Meat Products

By Members of the Research Staff of the American Meat Institute Foundation. (Series of Books in Agricultural Science.) Pp. x+438. (San Francisco and London: W. H. Freeman and Company, 1960.) 68s.

THE growth of education in the subject which has come to be known as food science has been handicapped by a lack of suitable texts. For this reason the publication of "The Science of Meat and Meat Products" is an event of some importance. Yet the book is more than a text. As its preface claims, it is no less than an attempt "to present the current scientific knowledge on meat and meat products, and to show how various scientific disciplines are applied in meat research."

In common with other foodstuffs, meat has attracted the attention of chemists, biochemists, nutritionists, microbiologists and others for more than half a century. The quickening tempo of research in recent years has both stimulated and been stimulated by the increasing industrial demand for fundamental information. The problem starts with the geneticist in breeding from the gene pools at his disposal the types of animal best suited for the varied purposes of use. It ends perhaps at the level of human nutrition; but between the beginning and the end diverse scientific disciplines have many parts to play.

With this field to survey within the compass of a modest 438 pages, the American Meat Institute Foundation has undertaken a substantial task. It is inevitable that an individual reader will find some topics treated less fully than he would have liked. Moreover, the various chapters were written by a panel of twenty-six authors, and some unevenness of treatment would seem inescapable. That the reader is not unduly conscious of multiple authorship in the circumstances is a tribute to the editorial board. Formal references have been wisely avoided, but at the end of each chapter a carefully selected list of source material is given to ease the path of those who would study further. The compression of factual information does not always make for easy reading, but the style throughout is lucid, and comprehension is aided by excellent illustrations.

The necessity for keeping the book in proportion has cramped the writers of certain sections, and it is to be regretted that space has been devoted to topics such as Michaelis-Menten kinetics and the methods of protein chemistry which will be familiar to most of its readers. The space saved by omitting such material might have been devoted to the anatomy of meat animals and to a fuller treatment of the relations between carcase conformation and meat quality. The average butcher is a better anatomist than some scientists engaged in the study of meat.

The indexing of such a book presents peculiar problems, and the index, although good, is not comprehensive and fails to list some of the important items considered in the text. Few misprints were noticed, apart from a very obvious one in the table of contents, but a curious mistake in connexion with federal regulations governing the use of ascorbic acid was noted on p. 359.

Notwithstanding these criticisms, this book is an important work which may become a standard text. It is an essential purchase for food science libraries, and a laboratory copy in British meat-packing plants might well contribute to improvements in practice in our own industry.

J. HAWTHORN

BIOGRAPHY OF *AUSTRALOPITHECUS*

Adventures with the Missing Link

By Prof. Raymond A. Dart, with Dennis Craig. Pp. xv+251+20 plates. (London: Hamish Hamilton, Ltd., 1959.) 25s. net.

PROF. Dart has brought together many of his controversial theories in this book, which is partly autobiographical, but mainly a biography of *Australopithecus*. The story begins with the discovery of the Taungs infant in 1924 and ends with a footnote on *Zinjanthropus* added while the book was in the press.

Nearly half the pages concern the 'osteodontokeratic culture', which has been Dart's main interest for 14 years. Only by proving that the Australopithecines were tool-makers could he resolve the interminable arguments as to their hominid or pongid status. Sceptics discredited the 'culture' as the work of bone-collecting hyenas, a myth which Dart took great trouble to disprove. His detailed analysis of bone fragments from Makapansgat revealed that the great majority were antelope mandibles and the distal ends of humeri. By comparing these finds with a similar bone 'industry' from a Middle Stone Age site at Kalkbank, he became convinced that the Makapansgat specimens were artefacts.

Whether one agrees with Dart's conclusions or not, he cannot be accused of drawing on too little evidence. The task of sorting thousands of tons of breccia, chiselling out the bone fragments and identifying them must have been formidable. Nor did he neglect practical experiments, such as reproducing the famous cannon bone 'apple-corers' which necessitated striking over a hundred blows with a bone fabricator. But to suggest that the Australopithecines went to such lengths to make scoops to convey pulped food to the mouths of toothless infants is surely to overestimate their technological skill—and our own credulity.

Dart's genius and persistence might be interpreted by some as impetuosity and obduracy. He makes no attempt to conceal his faults, of which the most serious is touchiness. He refused to study the Mapungubwe skeletons because "any report I might make on the remains would be regarded as prejudiced" (p. 68); and would not interpret the endocranial casts from Sterkfontein because of Hooton's remark that "a dispassionate interpretation of new fossil evidence is usually obtainable only . . . by persons not emotionally identified with the specimen" (p. 86).

Some of the causes which Dart took up with such enthusiasm found few supporters: the Eastern origin of Rhodesian mining and stone building; Mongoloid contacts with the Bushmen; the fire-making abilities of *Australopithecus prometheus*. But on several occasions he has been proved triumphantly right, notably over the tool-making capabilities of the Australopithecines—in stone. His unorthodox views and his imagination, no less than his discoveries, have had a most stimulating effect on anthropology. They are very apparent in this most absorbing and readable book, which is marred only by the poor quality of the drawings.

Sonia Cole

A NEW TREATISE ON PLANT PHYSIOLOGY

Plant Physiology
A Treatise. Edited by F. C. Steward. Vol. 2: Plants in Relation to Water and Solutes. Pp. xvii+758. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1959.) 22 dollars.

PLANT physiologists cannot complain of a shortage of literature designed to provide up-to-date information of the state of knowledge of the various branches of the subject. As well as a number of monographs on different parts of the subject there has appeared each year for the past ten years the "Annual Review of Plant Physiology" which has given summaries of recent advances in selected aspects of plant physiology, while about four years ago the publication of the "Encyclopedia of Plant Physiology" began, about a third of its projected 18 volumes having still to appear. Now we have the first volume of what is described as a treatise which is designed to cover the field of plant physiology in seven volumes. Although very much smaller in size than the "Encyclopedia", this new venture will yet be a considerable work when completed. How then is it to be appraised? According to the preface of this first volume to appear, it is intended not only to be a work of reference but also to give "a reasoned analysis of the status and development" of each subject discussed, and the readers for whom this analysis is intended are listed as "advanced and postgraduate students, teachers, research workers and investigators in other fields of knowledge, who need information about the present state of physiology".

This first volume to appear consists of seven articles, varying very much in length, by writers who have worked in the respective branches of the subject with which they deal. As is pointed out in the preface, each of these articles is affected by its author's own opinions. This should be borne in mind by the reader, for other workers in these same fields might have other opinions. For example the reviewer, who has had more than a casual interest in the salt relations of plant cells and tissues for nearly half a century, and who was concerned in some degree with earlier investigations on these relations, also has his own opinions, and it is clear that these do not always coincide with those expressed in the article on this subject in the volume under consideration.

Works of this kind, well produced and well bound, extending to several volumes and composed of a greater or less number of articles written by different contributors, have become the fashion. Of their value to the student there can be no doubt, but whatever their merits they have one character in common: they cost what seems to the reviewer quite a lot of money. This is no doubt unavoidable, but it probably means that in Great Britain at any rate they find their way mainly into the libraries of universities and other institutions and that comparatively few are purchased by students and teachers, who are not among the most opulent members of the community. If this should be so with the present volume it is to be regretted, as probably many plant physiologists would like to have it on their own shelves

Walter Stiles

VITAMIN B_{12}

Vitamin B_{12}
By Dr. E. Lester Smith. (Methuen's Monographs on Biochemical Subjects.) Pp. xii+196. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1960.) 15*s*. net.

VITAMIN B_{12} is unique in many ways. It took more than twenty years from the time of the discovery in 1926 that liver cured pernicious anæmia until the isolation in 1948 of the active principle, which we now know as vitamin B_{12}. The vitamin is active in fantastically small quantities; the body needs something of the order of one millionth of a gram daily. This is about one thousandth of the requirements of some of the other vitamins in the B groups. Vitamin B_{12} is the only vitamin which contains a metal in its very complicated molecule. It seems to be synthesized only by micro-organisms, yet in our diets it exists virtually exclusively in foods of animal origin. Its final isolation in 1948, almost simultaneously in the United States and in England, would no doubt have been even longer delayed but for the resources of the two large pharmaceutical companies which could work up one ton of liver to produce about 20 mgm. of red crystals.

Dr. Lester Smith, the Glaxo chemist who was responsible for the isolation in England, has produced the first book devoted entirely to vitamin B_{12}. It is a short book, and this is probably the reason for the only serious criticism one can make of an otherwise excellent survey. Some of it is so condensed as to make it difficult to understand at first reading; it becomes more of a reference book than a simple account of the subject. Of particular usefulness for reference is the description of the chemistry of vitamin B_{12} and its many relations; this is splendidly done by the author, who himself has contributed a good deal to its elucidation. On the other hand, a few errors and ambiguities—none of them at all serious—have crept into the description of the biological aspects of the vitamin. For example, the author cites the work of Morgan and Yudkin on the vitamin B sparing action of sorbitol, but this work in fact makes no reference to vitamin B_{12}. Again, how many readers know of the enzyme rhodanese? I have only one criticism of production: it is certainly difficult to print chemical formulæ so as to give the effect of three dimensions, but something better can be done than those given on pp. 36–37.

This is a book that every nutritionist will have to possess and use; and we shall look forward to new editions produced by Dr. Lester Smith to keep us up to date in the rapidly advancing knowledge in this field. I hope he will then be kind enough to indulge the prejudices of at least one reader, who believes that 'human' is an adjective and not a noun, and who also believes that there is a difference between the symptoms and the signs of an illness.

John Yudkin

Advances in Clinical Chemistry

Vol. 2. Edited by Harry Sobotka and C. P. Stewart. Pp. xiii+387. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1959.) 12 dollars.

TWO of the articles in this volume are primarily concerned with methods ("Paper Electrophoresis" by H. Peeters and "Automation" by W. H. Marsh). The four others survey certain selected biochemical fields. Dr. Peeters deals first with electrophoresis on strips and then with the less-familiar paper curtain electrophoresis. Factors underlying separations are examined in great detail and illustrated with many diagrams and tables. Much of the information is the author's original work which has been presented at the annual colloquia on proteins at Bruges. Dr. Marsh's article is timely in view of the increasing difficulties of obtaining personnel to cope with growing demands in clinical chemical laboratories. Simple as well as complex apparatus and processes are described and the article will be of special interest to those in charge of clinical chemical work. S. P. Bessman surveys the history, metabolism, measurement and pathological alteration of blood ammonia, and his article should stimulate interest in a subject the significance of which is not as widely appreciated as it ought to be. "Idiopathic Hypercalcaemia of Infancy" is a well-written review by J. O. Forfar and S. L. Thompsett, in which the clinical picture, biochemistry, aetiology and treatment of the disease, is covered. However, this article would possibly be more appropriate in a medical book rather than in this volume. E. J. Bigwood and associates provide a most valuable survey of amino-acid excretion in health and disease. Much of the data is quantitative and obtained by means of ion-exchange chromatography. Finally, "Bile Pigments in Jaundice" by Barbara H. Billing is an excellent account, including identification, chromatographic behaviour, methods of measurement and metabolism of these substances. Altogether, this well-produced second volume is full of interest for clinical chemists.

R. Consden

Traité Général de la Fabrication des Colles des Glutinants et Matières d'Apprêts

Par Dr. Maurice de Keghel Nouvelle édition, augmentée et remise à jour. Pp. ii+764. (Paris: Gauthier-Villars, 1959.) 7,000 francs.

THIS new edition does not appear to be any appreciable improvement on the original version. The ground to be covered by a single author—animal glue, vegetable adhesives, casein, synthetic resins, silicate adhesives, rubber, etc., in some sections including both manufacture and use—is so wide that full references to the sources of information are essential. No references are given throughout the book, the only indication of origin being a manufacturer's name for plant, and, very rarely, an author's name, without detailed reference, for some experimental method. What basic scientific information is included is, in the main, unrelated to modern work. As an example, the conversion of collagen to gelatin is given as:

$$C_{102}H_{149}O_{38}N_{31} + H_2O = C_{102}H_{151}O_{39}N_{31}$$

This type of approach was already being superseded forty years ago when the equation was given in the text-books of that time. To-day it is not merely wrong, but also neglects the whole development of the concepts of the chemistry of macromolecules of the past thirty years.

The descriptions of plant and of industrial processes also neglect many recent developments which have changed the position of whole sections of the adhesives industry. The very large number of recipes for adhesives of various kinds are presented uncritically, with no attempts to explain the significance or function of the components used.

Certain methods of test are included. These appear to be selected at random, no reference being made to the versions accepted by the national standardizing bodies.

Neither for the manufacturer nor for the user of adhesives can this volume be said to serve a useful purpose, and less-informed readers would be misled by its many omissions and out-of-date information.

A. G. Ward

The Hollow Universe

By Prof. Charles de Koninck. (The Whidden Lectures, Series IV.) Pp. xii+127. (London: Oxford University Press, 1960.) 12s. 6d. net.

THE author of these lectures, now so attractively issued in book form, was not hampered by any rigid terms of reference, but could discuss what he liked and how he liked. Such opportunities are rare, and reflect credit upon the founder and the establishment of his trust. The theme is not altogether new; it displays the anxieties which are common enough at the ways things are going in the intellectual world. In brief, if we are nothing more than "a mere collection of occurrences", there will be (at the best) little left to wonder at in the whole domain of natural philosophy and human thought. Maybe this is so, but it makes something like nonsense of life as we known it. Prof. de Koninck is a very sensible person, and, moreover, fully alive to the claims of the positivists. His point is that in mathematical physics and everything related thereto one can, and must, be utterly impersonal, and regard Nature as purposeless.

But this does not necessarily apply to the biological sciences in which it is argued (very forcibly, in the reviewer's opinion) that an organism—that is, something provided with 'tools'—is meaningless if devoid of any teleological characteristics whatever. Incidentally, it is maintained that concentration on the lowest forms of life is not the best way to build up an understanding of Nature, any more than it is epistemologically rewarding to seek for goals and ends in plants, however fascinating, one may add, are the problems of morphology.

Thus, we are left with the tremendous question of the fundamentals of biophysics, and the advance of computers. Nobody is likely to ascribe wholly axiological judgments to mechanical systems for some time to come. That these judgments remain seem to make it probable that the universe is not entirely hollow.

F. I. G. Rawlins

Theories of Figures of Celestial Bodies

By Wenceslas S. Jardetzky. Pp. xi+186. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd. 1958.) 45s.

ONE of the deepest mysteries of the universe is that everything in it rotates. This remark, by the late Sir Arthur Eddington, probably explains why the theory of figures of celestial bodies has exercised the minds of many famous mathematicians during the past century. The reader of the book under review may be surprised to find names such as Dirichlet, Liouville, Riemann, Poincaré, Volterra, and more recently, Kahler, Liapounov, Lichtenstein and Wavre associated with the subject, but this list alone indicates that the problems involved are fundamental and of the highest status. Liouville published three papers on the theory during the years 1845–1855 and Dirichlet and Riemann each published a paper in 1861. Since about this time a great deal of research has been carried out in this field and the book by Prof. Jardetzky gives a careful and faithful account of the developments that have occurred.

There are two parts, one dealing with figures of equilibrium of a rotating fluid mass, and one with other figures. The former is classical and describes the most exact methods available for determining the figures. It includes chapters on the methods of Poincaré, Liapounov, Lichtenstein and Wavre. The second part covers zonal rotation, varying figures, systems composed of fluid and rigid parts, fluid mass and centres of attraction, and figures of compressible masses. This part takes into account more physical features than the first and is to that extent more realistic, but its results are not so rigorously developed and many of the problems still await solution.

One really valuable feature of the book is that it covers material which, for the most part, was formerly tucked away in obscure or old journals not generally available. The author was the last pupil of Liapounov and thus is well qualified to bring into the light the work of his teacher in this field. He has himself contributed greatly to the subject, and there are references to his work throughout the book. Anyone working in this field will want to consult the bibliography, which is unusually comprehensive.

L. S. GODDARD

The Jaws and Teeth of Primates

Photographs and Commentaries. By W. Warwick James. Pp. xii+328. (London: Pitman Medical Publishing Co., Ltd., 1960.) 105*s*. net.

THIS book is essentially an atlas of more than two hundred photographic illustrations of the skulls and teeth of representative genera of the modern Primates from tree-shrews to man, each series of illustrations being accompanied by a brief summary of the main features of the dentition. As such, it will provide a convenient work of reference for those who have not ready access to original material in museum collections. The photographs are excellent and have been most skilfully reproduced. The author's notes on the general characters, habits and habitat of each genus are derivative, but unfortunately too often based on early statements in the literature which have been superseded in more recent studies. A number of his observations, also, are surprising and even misleading—for example (in reference to the teeth of 'civilized man'), "Their beauty is regarded as their chief attribute"; in the Prosimii "the cerebral hemispheres are only slightly convoluted"; "Very few fossil Primates have been found in North or South America"; gibbons "live in large colonies which may contain fifty to a hundred members"; "Man in his present state, both mentally and physically, is very different from his ancestor a few thousand years ago"; and so forth. The appendixes on tooth development and the articular eminence raise some interesting points, but are too brief to permit any conclusions of value. Although the text contains statements open to criticism, I would repeat my main assessment, that, considered simply as a photographic atlas, the book certainly deserves commendation as a useful work of reference.

W. LE GROS CLARK

Africa's Place in the Emergence of Civilisation

By Prof. Raymond A. Dart. (The Van Riebeeck Lectures.) Pp. 96. (Johannesburg: South African Broadcasting Corporation.) 2*s*. 6*d*.

THE name of Prof. R. A. Dart, who until recently was professor of anatomy at the Witwatersrand University, will always be associated with the discovery of the Taungs skull. At first some of his ideas were scouted as being fantastic, but of recent years new discoveries have brought to light other ape-men of a very early age and many of his notions have been vindicated. A short while ago he was asked to inaugurate the Van Riebeeck Lectures of the South African Broadcasting Corporation, and "Africa's Place in the Emergence of Civilisation" is the result. Prof. Dart is tremendously impressed with the "Miraculous Community-building effects of fishing upon humanity", and it is fair to say that this theme is central to the book. But naturally the first lecture deals with earlier times and the cultural differences between an ape and a first real man. Here perhaps a saying of Schweitzer to me may be of interest; Schweitzer has kept young gorillas and other anthropoid apes in West Africa and he stated that the difference between a gorilla and a man is minimal compared with the difference between a gorilla and any other anthropoid ape. Chapter 2 is concerned with the appearance of true civilization in the Near East; and then we come to fishing, which, of course, involved boats and boat building. But while this helped forward the march of progress, true civilization is based, surely, on community life and law. May I interpolate here the suggestion that civilization starts in the community life of the village but does not come to real fruition until the development of the towns, and that in Africa south of the Sahara there seem to have grown up no real towns before the coming of Europeans; this may be the fact that has caused Africa to lag behind China, northern India, the Near East and western Europe in the evolution of true 'civilizations'. Prof. Dart does not intend his little work to be the last word on an immense subject. But, just as he himself is stimulating to talk to, so his book is stimulating to read even if, for the moment, everyone may not agree with all he says.

M. C. BURKITT

Laboratory Testing in Soil Engineering

By T. N. W. Akroyd. (Geotechnical Monograph No. 1.) Pp. xx+233+32 plates. (London: Soil Mechanics, Ltd.). 50*s*. net.

MR. AKROYD'S book has been available long enough for quotations from technical reviews to appear on the cover of this edition. All, quite rightly, welcome it as a comprehensive survey, plentifully illustrated by photographs, line drawings and copies of work-sheets. It will be useful to consulting engineers who need a complete account of the kinds of test available, the problems for which the tests are helpful, and the snags that may arise. It could be useful in soils laboratories—teaching or research—where there is some interest in soil as an agricultural raw material.

H. L. PENMAN

CHROMOSOMES AND THE THEORY OF HEREDITY*

By Prof. C. D. DARLINGTON, F.R.S.
Botany School, Oxford

(1) Morgan's Discovery

THE crisis of the struggle in the scientific world over the chromosome theory of heredity was reached in the 1920's when Morgan's views became the subject of dispute. Morgan, with his collaborators at Columbia University, had carried out breeding experiments with the fly *Drosophila*. He claimed that by these experiments he could show that heredity, as long suspected, was indeed carried entirely by the chromosomes. It followed that these minute bodies in the cell nucleus were to be held responsible for the whole character of every living thing, plant or animal, man or microbe; and the course of evolution from the beginning had been determined by changes in these chromosomes. It was a complete scheme of determinism on Omar Khayyam lines.

This theory aroused misgiving and contradiction in many countries, especially among older men who might know the fly but certainly did not know its chromosomes. Before we look at their arguments, let us see what Morgan, and Mendel before him, had done.

Mendel had found that if he crossed two races of peas differing in two respects, as it might be $AB \times ab$, the hybrid gave germ cells of four kinds in equal numbers: *AB*, *Ab*, *aB* and *ab*. Free assortment, random recombination, independent segregation were the explanations given for this behaviour. Assortment of what? Assortment of certain 'elements' carried in all cells and passed to the germ cells. Morgan, however, beginning in 1910, found that in the fly often less than half the germ cells were of the new types, *Ab* and *aB*. The proportion was characteristic of the particular pair of elements. Assortment was not free. The elements were linked; and, if the hybrid fly happened to be a male, the linkage was complete: the elements were held together in one block.

At this point Morgan recalled that the previous year, the cytologist Janssens at Louvain had made a general proposal about chromosome behaviour. He had noticed that after the pairing of maternal and paternal chromosomes in germ cell formation they fell apart but remained touching or attached at various points which he called "chiasmata". At these points, Janssens suggested, the mating chromosomes might exchange parts by breakage and reunion. Such behaviour would give a statistical association or linkage of elements in the same chromosome of a kind already to be suspected from Bateson's breeding experiments. Conversely it would lead to the formation of new chromosomes by a recombination of parts.

Taking Janssens's hint, Morgan and his collaborators proceeded to make crosses between pairs of flies differing in many pairs of respects. They found that hundreds of elements could on this assumption be fitted into the four observed pairs of chromosomes of *Drosophila*. Moreover, if the proportion of re-grouping or crossing-over was itself assumed to be related to the distance apart of the elements along each chromosome, they found that the whole assembly fitted into fixed linear orders. Thus the elements of heredity, or using Johannsen's word the genes, could be put on a map which, like other maps, showed one how to find one's way about.

It soon seemed reasonable to advance from these direct inferences to more general principles. Morgan argued that all heredity in all organisms was carried by chromosomes as it was in *Drosophila*. Further, all chromosomes were composed of units of crossing-over or mutation which might be known as genes. Hence, he appeared to argue, the genes would add up to give the whole of heredity; and the differences between them would add up to give the whole of variation and of evolution.

(2) The Opposition

Morgan's "Theory of the Gene" appeared in 1926; its reception in England could scarcely have been more unfavourable. Seven men might have been willing to assert their belief in the chromosome theory and give their reasons for it. But against this view there were seven hundred who held a contrary opinion. The supporters felt liberated by the new theory: its opponents felt confined and oppressed by it. The grounds they gave for their opposition were both general and specific.

The general objections were that the theory was naive and mechanical and yet self-contradictory. For it was both statistical and deterministic. It left too much room to chance yet no room to free will. In evolution, moreover, its hard particulate basis shut out the hope of any soft Lamarckian adaptation. The Lamarckian principle, we must remember, was at that time generally maintained by naturalists and physiologists and assumed by medical and social scientists. Even philosophers had their opinions, and they were on the Lamarckian side. Yet there was no room in this picture for the Lamarckian emblems, the giraffe, the salamander, or the midwife toad.

The more specific objections to the chromosome theory were also very various. The assumption that the chromosomes were alone responsible for heredity left a gap in our theory of development. Is not heredity merely a repetition of development? Yet this theory of heredity almost ignored development, and it was based on a single organism—a fly with a most disorderly development of its own. The chromosome theory also left a gap where the cytoplasm should be—where indeed European workers had found evidence of determination. Loeb, with his unfortunate idea that the cytoplasm carried the solid basis of heredity while the nucleus bore only a few frills, provided a line of defence for weaker opponents of the chromosome theory.

---

* Substance of a Royal Society Tercentenary Lecture delivered on July 20.

Again it was pointed out, quite rightly, that the gene mutations of *Drosophila* could not be representative of natural variation for they were in their effects both disadvantageous and discontinuous. In the first respect they contradicted the helpful mutations of the evening primrose, *Oenothera*. In the second respect they failed to explain the universal property of continuous variation. As for the chromosomes themselves, did they not at the end of every cell division dissolve and disappear into that bag of fluid, the nucleus? As for crossing-over, the foundation of Morgan's interpretation, it was supposed to happen only in one sex and not in the other. But who had ever seen it happen anywhere? Crossing-over, like the genes themselves, was a stroke of fancy, a mathematical artefact invented to salvage a broken hypothesis.

With regard to these chromosomes, it was true, there were a variety of accounts of what they did. The two cell divisions known as meiosis, when the germ cells were formed, were especially disputable. Some believed that there were general rules; others that there were many kinds of meiosis in different groups of plants and animals. Most believed that, if there was a rule, it was that the corresponding chromosomes from the two parents paired as threads side-by-side. But a few stoutly maintained that chromosomes in the nucleus were in an endless chain which split up crosswise into segments to give $2x$ single chromosomes at mitosis, x double chromosomes at meiosis, and, by a freak of Nature, $4x$ chromosomes at mitosis making a new tetraploid. Clearly this view was of no help to those who believed that the chromosomes made heredity and were differentiated in linear structure; but it was a help to those who did not think anything of the kind. Such differences of opinion—which were described in text-books, taught in universities and expounded in theses—created a verbal and literary jungle which had to be cleared before any general theory could be discussed.

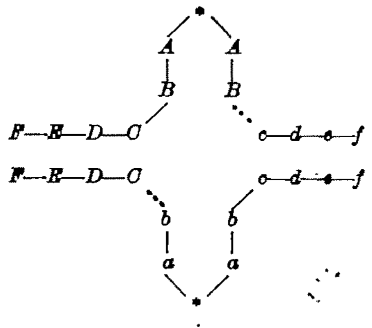
Finally, there was one specific objection which no one seemed to make. It was that genes were inferred to exist from breeding experiments with 'characters'; or more precisely, from studying the inheritance of differences of character when different parents were crossed. Yet the whole of heredity, of the genotype, was supposed to be made up of genes added together. There was a concealed gap between the analytical or differential gene and the integral genotype. In looking at the chromosomes one could see that they added up to make the nucleus. But their differences, their variations, were visibly of many kinds and degrees. The gap was revealed. How could it be bridged? Not, as it seemed to me, by pretending that it did not exist. It was necessary to work out a system of understanding life in terms of chromosomes, a system independent of experimental breeding, a system which would stand on its own feet. In this view I was strengthened by one man's opinion. "Cytology", Karl Belar said to me in 1928, "should not be the *ancilla* of genetics". That was just what I thought.

(3) Crossing-over and the Chiasma

Belar had shown that mitosis and the chromosomes themselves had a universal character, a character which must underlie the uniformity of development of plants and animals and protists. Here was a great and necessary step forward. In genetics, as in geology a century earlier, uniformity was bound up with evolution. Cytologists and geneticists too, so far as they took the chromosomes seriously, therefore liked to think that the same such universal character was true also of meiosis and underlay some uniformity in heredity. But *Drosophila* itself, with crossing-over at meiosis in the female but not in the male, faced us with the gravest objection to this view. It was possible to evade the issue for the time being. It was possible to begin with the simplest material offering experimental tests by purely chromosome criteria. For this purpose polyploid plants with large chromosomes, tulips and hyacinths, were admirably fitted. They revealed several unexpected principles. The important ones, in the present connexion, concern the chiasma.

At a certain stage in the beginning or 'prophase' of meiosis, like chromosomes come together as threads side-by-side in pairs. The association is limited to likes: it is chemically specific; and it was, I found, limited to pairs even when there are three or four of a kind. At a later stage the paired chromosomes reproduce forming double threads and at the same time fall apart. But when they do so they stick at certain points, as Janssens had said, the chiasmata.

Why do they fall apart, in one sense, and stick together, in another? Their structure gave the answer. Contrary to Janssens's view, the chiasmata always had the same structure: they were exchanges of partner between half-chromosome threads, chromatids as we call them. Further, these exchanges could be shown, on internal, cellular, microscopic, evidence to be invariably connected with a previous crossing-over between chromatids of the partner chromosomes. On the simplest assumption, therefore, chiasmata were determined by such crossing-over. The arrangement of four chromatids could be shown in a diagram that was at once genetic and cytological in its implications. With capital and small letters in sequence for the pairing chromosomes, an asterisk for the mechanical centre, and dots for the points of breakage, the diagram would be as follows:



Thus from two chromosomes, *ABCDEF* and *abcdef*, two new chromatids, *ABcdef* and *abCDEF*, had been formed, and the four chromatids would pass as chromosomes into the four germ cells formed by meiosis. The existence of these four cells would, as Janssens had put it, be justified by each of them being a unique combination of available genes different from the rest.

One could not of course prove that this principle was universally true (in those days most biologists believed that propositions ought to be 'proved'); one could merely hope to render it increasingly probable. This hope was gradually realized. The critical configurations of several chromosomes united by, or interlocked with, successive chiasmata, the comparisons of frequencies and distributions of chiasmata and crossing-over in different organisms, in polyploids, in hybrids, with inversions and interchanges of segments of chromosome, in plants with defects of chromosome pairing and of sexual reproduction, these all helped to carry conviction. Even in *Oenothera* the occurrence of chiasmata, the inference of crossing-over, could be used to explain the modes of inheritance and the origins and kinds of mutations.

The solution of the problem of crossing-over was, however, obstructed by another, to me, unexpected but inseparable development. The study I had made of meiosis, and my interpretation of what a hundred others had seen in a great variety of plants and animals, made it clear that the chiasma had consequences which were as important as its causes. People had supposed that the chromosomes were paired at the first metaphase of meiosis because they were, in a mysterious sense, attracted to one another. This was, they thought, the climax of the sexual process. What could be more natural? But I had found that, after pairing as single threads, the chromosomes fall apart as double threads. They do not attract, they repel one another after they become double; and they are held together only by chiasmata, by the exchanges of partner between their chromatids, after crossing-over. When pairs of chromosomes fail to form chiasmata, whatever the cause, the consequence is that they lie on the spindle, unconnected and unorientated. They then fail to pass to opposite poles. Without chiasmata meiosis itself, with Mendelian segregation, the reduction of chromosome number and the alternation of haploid and diploid in the sexual cycle, all these fail to ensue.

Thus there was, in my view, a universal causal sequence: crossing-over ⟶ chiasmata ⟶ chromosome pairing ⟶ segregation and reduction ⟶ sexual reproduction.

This reversal of the mechanical interpretation of meiosis made it possible to describe meiosis in the same physico-chemical terms as mitosis. But what mattered first were its genetic implications. The new principle seemed to be true of all plants and animals (except male *Drosophila*). It therefore meant that meiosis and crossing-over had come in together, at one step. Crossing-over from its origin must have been co-extensive with sexual reproduction. What Morgan had hoped to imply I was now forced to assert. The reason why the chromosomes were divisible into units of genes was that everywhere their division into such units was a condition of meiosis and hence of sexual reproduction. This, of course, made sense in terms of selection, adaptation, and the evolution of sexual reproduction itself. For if the chromosome were not divisible into genes, if it were not capable of crossing-over, it would be inherited as a block and no genes could be revealed either to the geneticist by his experiments or to Nature by her selection. The original system would never have survived.

(4) Evolution and the Cell

It will be seen here that an evolutionary point of view was beginning to force itself into my argument.

There were several reasons why this should have happened to the student of chromosomes, by no stretch of the imagination but by hard necessity. While the experimental breeder could sort out linkage in one species, the chromosomes could reveal chiasmata in a hundred species and in every group of plants and animals. While the experimental breeder himself decided how his plants or animals should breed, the chromosome man had to pick up his cells and discover how Nature had bred them, and why, and with what effect. These were two reasons. But a third was even larger. It was that through the chromosomes there is continuity between successive generations. To the naturalist and to the experimental breeder the organism is an independent discontinuous entity. To the cytologist it is part of a continuous process. Cell division is always a step between the past and future: it is always adapted to meet conditions which do not yet exist, to produce progeny which are irrelevant to their parent's success.

Oenothera first brought this home to me. In its evolution there had been interchanges between different chromosomes, each of which succeeded by virtue of its selective advantage over its predecessors. But success depended on whether plants were inbred or outbred. Thus the hereditary mechanism and the sexual mechanism, the means of distributing and recombining differences and the means of bringing them together, must be bound up together in one system, a genetic system. In a genetic system crossing-over of chromosomes is no good without crossing of germ cells, without outbreeding. The two processes must be adjusted to one another. They must also be adjusted to the needs, not of the individual, but of the breeding group and, more particularly, of its posterity.

A second example was in the male *Drosophila*, with its suppression of crossing-over. In these flies the male, I found, had contrived an anomalous kind of meiosis without crossing-over. The chromosomes paired and separated without needing to form chiasmata. The breeding and the chromosome observations thus agreed. But how had an otherwise universal rule come to break down—and break down in the very species of organism in which the rule was first brought to light?

The reason is obvious as soon as it is pointed out. In the vertebrates or flowering plants the genes in the chromosomes are recombined once in every sexual generation. This may be once in ten months or ten years. But in the short-lived flies it happens once in ten days. That is why from the whole animal kingdom Morgan chose to work with them. But to recombine genes so often does not give any combination a chance of being properly tested. Far better to let the genes recombine in one sex and pass unrecombined through the other sex, down the other line. It is an admirable solution: new things can be made, but good things can be kept.

In the evolution of the flies it was not therefore surprising that a new type of meiosis had been developed in one sex—it had to be the heterozygous sex—in which crossing-over was suppressed. The genetic system would benefit from this modification. The original type of meiosis, on the other hand, was the common ancestral type still found in all species of plants, animals and protista, a type of nuclear division which had arisen at the origin of sexual reproduction, a type with a uniform physico-chemical character.

At the time this speculative conclusion seemed to be rash. To-day, however, we can clearly go further.

The brilliant work that is now being used to reveal the genetic structure of fungi, bacteria, bacteriophages, and other viruses makes it indeed necessary to go further. We have to say now that crossing-over of gene sequences, or nucleotide sequences, is the original property of all systems capable of evolution: and we may add that sexual reproduction, as we ordinarily understand it, is the structure built around crossing-over which has made the higher organisms possible.

This view turned genetics upside down. In the short term one could still see fertilization as the focus of life's processes. For it is at this moment in the higher plants and animals that the individual is created. But in the long term the focus was shifted to the act of crossing-over and the origin of the chiasma. For this is the moment when, we may say, the gene is created. On this event all the processes of evolution converge and from it they all diverge.

(5) Determination and Uncertainty

At an early stage in the discussion of crossing-over, the opponents of the chromosome theory objected that there was no visual or direct evidence that chromosomes did or could cross over at meiosis. When this evidence was provided they objected that there was no reason why it should happen. Fortunately the mechanical reasons were by this time only too evident. Chromosomes which pair as threads always coil around one another. Just as pairs of textile fibres spun under torsion release a part of their torsion by coiling around one another, so do the chromosomes. The part of their torsion released is in equilibrium with the rest which is stored; it is available to break the chromatids and to untwist them to a position where their broken ends can recombine in new combinations. The specificity in pairing of genes and of parts of chromosomes and the observed release of torsion at the chiasma provide for the time, place, and action, of the event inferred in *Drosophila* and of the result seen in the chiasma.

Experiments with nucleic acid starvation later indicated that the nucleic acid component of the chromosomes was the means of developing their torsion. I therefore assumed it to have the structure not of a straight column but of a spiral staircase, an assumption which has been vindicated with beautiful precision by Watson and Crick. How the molecular spiral works in detail, however, is a question we must ask later, when we have a more elaborate molecular model of the paired chromosomes.

What must be discussed now is the fact that this breakage, this crossing-over, can occur at hundreds or thousands of different places along the chromosome: indeed by one definition between any pair of genes in the whole sequence. But in a particular pair in a particular cell it occurs at only a few points, from one to a dozen; and there are conditions, even in *Drosophila* itself, where it seems to be almost fixed.

This situation, in our experience of the statistics of causal relations, seemed to be unique and significant. Its mere mechanics was easily understood. The frequency and distribution of crossing-over is characteristic of the organism. It can be regulated by the organism, by its heredity. If the chromosomes that are going to pair are regularly placed side by side in the nucleus, which sometimes happens, the amount of twisting they develop is regularly distributed and hence the crossing-over. If the chromosomes are irregularly placed, as they usually are, the crossing-over will be irregular and uncertain, as it usually is.

Thus the irregularity of crossing-over, which gives the characteristic variety of progeny in sexually reproducing organisms, is something controlled. Like the weather it shows uncertainty. But, like the weather also, we can predict it so far as we can expect to predict it. Its failure, as well as its normal conditions, show that it is a determined uncertainty. Indeed in asexual reproduction all uncertainty can be removed, and frequently is removed. Its general survival throughout the plant and animal world therefore shows that the uncertainty of crossing-over is original, is organized, and is of adaptive value. Through it indeed meiosis acts as a means of generating uncertainty.

To put the matter in another way: it is a paradox that the gene which is an organ of determinacy in life exists by virtue of a process of apparent indeterminacy. But when we examine it we find that the indeterminacy is spurious. It has been put there (if I may diverge from the present argument) by natural selection and for natural selection. It has been put there as a necessary complement of the uncertainty of the gene's mutation: together they produce adaptive variation.

The discovery of how crossing-over happens had long-range consequences beyond the previous limits of genetics. For it enabled us to split up the processes of life into two parts. First there are those concerned with determining the character of individuals. These are processes of physiology in which the greatest certainty of determination, the strictest predictability in reaction with the environment, a chemical determinism, is achieved; and secondly there are the processes of meiosis. These, reinforced by the chances of fertilization which are derived from them, determine the differences in character of individuals. They are the processes of classical genetics in which the greatest uncertainty of determination is organized and achieved.

This contrast, as I believe, between two kinds of process—the one deterministic, the other spuriously non-deterministic—also provides one of the several ways of splitting genetics into two. It means that instead of speaking of the laws of heredity, as the early Mendelians were fond of doing (making biology echo the physics of the time), we should speak rather of the 'paradoxes' of genetics. For heredity is a relation between parent and offspring which is variably compounded of the certain and the uncertain elements, according to how like the parents or grandparents may have been; indeed according to the effects of their system of breeding.

(6) The Continuing Issue

I have given an eye-witness account of a battle. I believe it is a battle that we won. The pursuit of the enemy has, to be sure, taken us far away from the original site of the conflict; and it could have taken us much further with the elasticity of the gene, the organization of the chromosome or the physiology of the nucleus. But the site of the struggle matters less than its purpose. The enemy, although defeated and dispersed, has not been destroyed. They will, in my opinion, have to be fought many times again. For mankind, if it happens to take note of the argument, will not willingly admit that its destiny can be revealed by the breeding of flies or the counting of chiasmata.

STREAMING IN CYTOPLASM DISSOCIATED FROM THE GIANT AMŒBA, *CHAOS CHAOS*

By Prof. R. D. ALLEN, J. W. COOLEDGE and P. J. HALL
Department of Biology, Princeton University, Princeton, New Jersey, U.S.A.

THE driving mechanism of amœboid movement (and its accompanying cytoplasmic streaming) has always been considered to be a property of the amœboid cell as a whole. We wish to report new findings which demonstrate that the cytoplasm can be removed from an amœba in a state in which it displays continuous and vigorous streaming *in vitro* for periods as long as an hour. Our experiments vividly demonstrate the inadequacy of the sol-gel or ectoplasmic contraction theory of amœboid movement[1,2], and lead to the conclusion that the cytoplasm of amœboid cells is structurally organized into subcellular 'units of streaming', the nature of which will be discussed here.

The phenomenon of persistent, continuous streaming in the cytoplasm of ruptured amœbæ (*Chaos chaos* and *Amoeba proteus*) was described briefly by the senior author in 1955 (ref. 3). Since that time there has been no hypothesis to explain this phenomenon, and a more complete account of it was postponed until a satisfactory hypothesis could be tested. The recent development of the 'fountain zone contraction theory' of amœboid movement has offered for the first time a satisfactory explanation for several perplexing aspects of amœboid movement[4,5]. According to this theory, the endoplasm begins to contract actively (that is, develop tension) as it enters the 'fountain zone' just posterior to the hyaline cap, where it becomes everted to form the ectoplasmic tube. The tension developed between the anchored advancing rim of the ectoplasmic tube and the movable endoplasm displaces the latter anteriorly. Continuous streaming is maintained by propagation of the contraction posteriorly along the endoplasm at the same velocity as that at which the endoplasm advances relative to the pseudopodial tip. At the anterior end of the cell the contraction phase of the contractility cycle expresses water (and solutes) to form the hyaline cap. The hyaline cap fluid must then be returned to the recruitment zone (tail endoplasm), where it is believed that the extension phase of the contractility cycle occurs[5]. The mobility of the plasmalemma with respect to the ectoplasmic tube[4,6] demonstrates the existence of a fluid channel (the hyaline ectoplasm) which could serve to transport the hyaline cap fluid to the posterior portion of the cell. The endoplasm has been shown to possess structure sufficient to transmit tension[7,8]. The details of evidence on which the fountain zone contraction theory is based is being presented elsewhere[6].

With the fountain zone contraction theory in mind, we have re-examined the phenomenon of streaming in cytoplasm dissociated from the amœba and have obtained quantitative data which satisfy many of the predictions of the fountain zone contraction theory.

Cytoplasm is freed from the cell by rupturing the cell membrane while the amœba itself is held in a quartz capillary to prevent the cytoplasm from becoming dispersed. The most successful method is to draw an intact amœba carefully into the fine bore of the capillary and then to shatter the capillary with a sharp scalpel under a pool of paraffin oil. The oil seals the capillary at both ends, thereby trapping the cytoplasm in a closed container isolated from outside forces. The capillary is drawn in two stages under an oxygen flame: first, from 6 mm. inside diameter to 1–2 mm., and then in a smaller flame to 75–200μ.

The experiment is easy to perform; students in the cellular physiology course at Princeton usually succeed after a few attempts in obtaining dissociated cytoplasm preparations which stream continuously

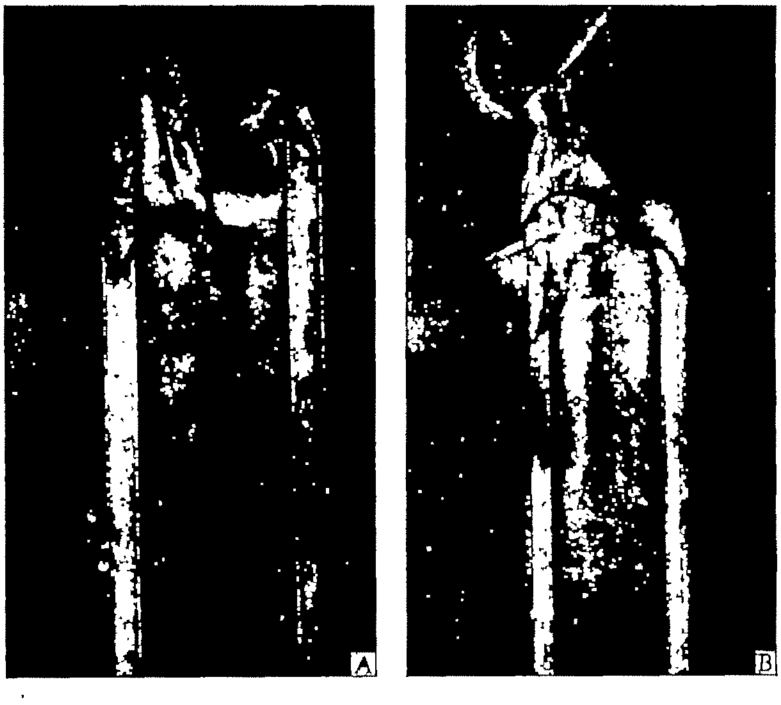


Fig. 1. Photographs of actively streaming cytoplasm dissociated from the giant amœba, *Chaos chaos*, contained in a broken capillary submersed in a pool of paraffin oil. (*A*) a preparation in which the capillary was shattered at the ends of the amœba to form a protoplasm–water interface. The marker is 50μ long. (*B*) similar to *A*, except that the capillary was shattered peripheral to the ends of the amœba. The arrow shows one of the loops of cytoplasm which stream out into the water and return to the main cytoplasmic mass (see text). The marker is 10μ long

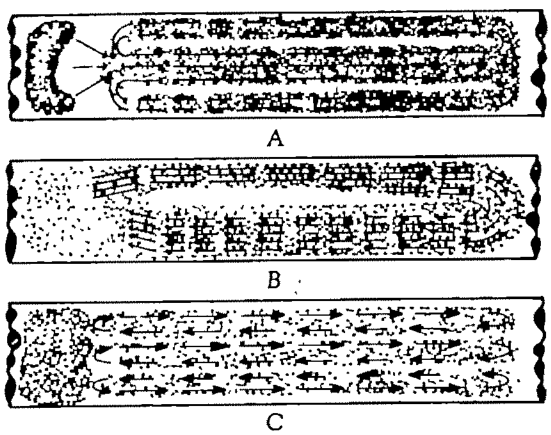

Fig. 2. Diagrams to show: (*A*) the fountain streaming pattern of stage I, note the remnants of the plasmalemma on the left side of the diagram; (*B*) stage II, showing the loop-streaming pattern; (*C*) stage III, after division along the longitudinal axis of some of the loops has occurred to increase the number of streaming units

for a half-hour or more after rupture of the cell. The only difficult part of the procedure is to draw the amœba into a sufficiently narrow capillary without rupturing its membrane prematurely. It is also essential that the cell fill the bore of the capillary, in order to prevent excessive dilution of the cytoplasm with water or other aqueous medium. It seems to make little difference to the outcome of the experiment whether the capillary is shattered directly over the two ends of the amœba (as in Fig. 1*A*) or slightly peripheral to the amœba (Fig. 1*B*), as the shock of breaking the capillary usually is sufficient to rupture the plasmalemma. The dissociated cytoplasm seems to stream equally well whether in contact at the ends with oil or water.

While it is possible to perform this experiment with any large, free-living amœba, *Chaos chaos* cytoplasm displays the most vigorous movement and 'survives' for the longest periods, ranging from 10 min. to an hour. Our best results have been obtained from *C. chaos* which were raised in Pringsheim solution[6], fasted 24 hr., washed in ion-free water, and cooled to 2° C. for about 12 hr. prior to an experiment. Amœbæ treated in this manner begin to stream within minutes after return to room temperature, and for a half-hour thereafter tend to remain monopodial. In this condition they are more readily drawn into capillaries without premature rupture. None of these treatments is absolutely necessary, and, in fact, the experiment will work with amœbæ taken directly from wild cultures. The low-temperature pretreatment renders the cells less fragile during transfer to capillaries, and the ion-free water reduces the tendency of the cytoplasm to become vacuolated following rupture of the plasmalemma.

Whether or not the cell exhibits streaming prior to rupture of the plasmalemma, the shattering of the capillary results in vigorous streaming which may reach a velocity double that in the intact cell.

The pattern of streaming usually goes through at least two of three recognizable stages during its 'survival' within the capillary. In the first stage, the cytoplasm circulates in the 'fountain pattern' typical of that seen in intact cells which are unable to become attached to a solid substratum. During this stage, any remnants of the plasmalemma are transported by the outer or 'ectoplasmic' stream to the former posterior end of the cell, where they can often be seen as a folded structure (Fig. 2*A*).

Within the first few minutes, the second stage of streaming begins by the appearance of an even number of 'units of streaming' which pass back and forth in a more or less orderly manner. Detailed observation of these 'units' shows that they are, in effect, bands or loops of cytoplasm, the bends of which are located usually at the former anterior region of the cell (Fig. 2*B*). It is difficult to determine how the change from the fountain pattern to the loop pattern occurs, but it seems likely that the cytoplasm breaks up into what correspond roughly to radial sectors. The units of streaming are definitely not channels through which 'plasmasol' flows, for solid cylinders of streaming cytoplasm are coherent and do not disperse in moderate amounts of water (see Fig. 1). They exhibit 'plug-flow' velocity profiles remarkably similar to those shown by the endoplasmic stream of the intact cell[7]. Sometimes thin cytoplasmic strands, recognizable only by moving rows of inclusions, come out into the water at the ends of a preparation similar to Fig. 1*B*, and follow a U-shaped course through the water and back into the main mass of dissociated cytoplasm.

During the third stage (Fig. 2*C*), there is a marked retardation of streaming velocity and a tendency (not seen in all preparations) of the units of streaming to divide longitudinally or 'tear'. This 'tearing' of the cytoplasmic structure appears to be a result of the development of unequal tension from contraction in the cytoplasm. The tension is relieved by tearing along a longitudinal fault in each streaming unit, resulting in its division into two units which thereafter move independently. The thinnest streaming units produced by such divisions might be called 'fibrils', although they are visible only as a linear aggregate of particles which move in single file.

If it is assumed that the U-shaped bands of cytoplasm arise from radial division of the fountain streaming pattern, it can then be shown that these units of streaming behave as predicted by the fountain zone contraction theory. In order to relate the behaviour of the units of streaming to the events in the intact cell, we shall refer to the cytoplasm approaching the bend of a loop as the 'endoplasmic arm' of the loop and the cytoplasm receding from the bend as the 'ectoplasmic arm'. This designation appears justified from the velocity profiles across the adjacent ecto- and endo-plasmic arms of a typical unit of streaming shown in Fig. 3. The velocity profile across the endoplasmic arm is remarkably similar in shape to that across the endoplasmic stream of the intact cell, as measured by Allen and Roslansky[7]; that across the ectoplasmic arm is flatter, as expected of a more rigid gel. The different velocity profiles almost certainly indicate a difference of consistency between the less rigid endoplasmic arm and the more rigid ectoplasmic arm of the loop, even though the profiles cannot be interpreted strictly in terms of classical flow theory (cf. ref. 7).

The fountain zone contraction theory predicts that the endoplasmic arm should shorten and thicken in passing through the bend. That endoplasm does shorten is shown by the fact that it is displaced toward the bend at 2–3 times the velocity at which the ectoplasmic arm recedes from the bend. (Velocity ratios of greater than 1 and less than 2 were recorded on film, but the positions at which these ratios were recorded were too far from the bend to be certain that the bend had remained stationary. No case has

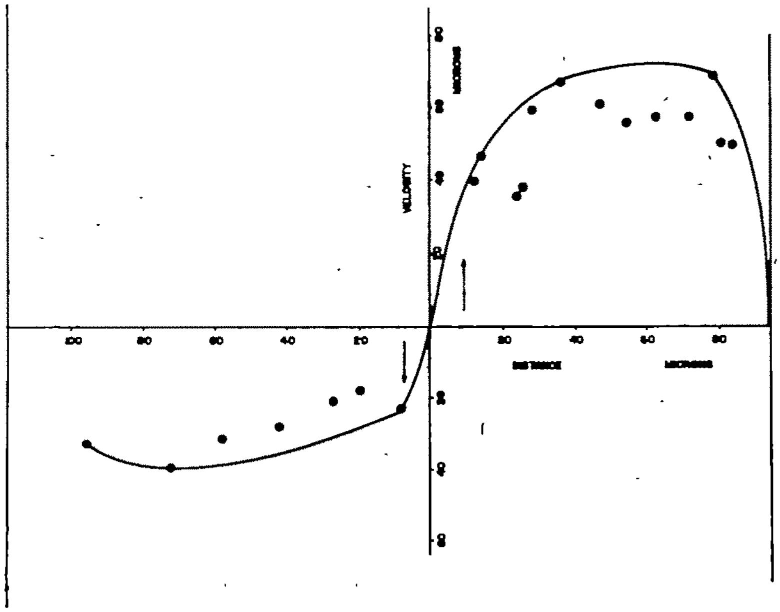

Fig. 3. A velocity profile across the endoplasmic (right) and ectoplasmic (left) arms of a broad, U-shaped loop of cytoplasm, measured approximately 150μ posterior to the bend. Note that the maximum velocity of the endoplasmic arm (streaming toward the bend) was approximately double that of the ectoplasmic arm (streaming away from the bend). The sum of the velocities was about twice the velocity of endoplasmic streaming of intact cells

been found of more rapid streaming away from the bend than toward it. The same velocity relationships hold true in the intact cell (see Fig. 4).) The shortening must occur where the velocity decreases; Fig. 4 shows that this decrease of velocity occurs at the junction between the endoplasmic arm and the bend. In favourable cases it has also been possible to measure a pronounced thickening of the cytoplasm in such a unit of streaming as it passes through the bend. In the example represented by Fig. 3, the cross-sectional area of the ectoplasmic arm was 3·8 times that of the endoplasmic arm, based on measurements of diameter. These changes in length and cross-sectional area are similar to those which have been shown to occur in the intact cell[5].

Besides the geometry changes mentioned above, there are more direct indications that a tension-producing contraction occurs at the bend of these units of streaming. Of particular significance is the fact that when streaming of cytoplasmic loops occurs in spurts, activity can be detected first at the bend of the loop, where a conspicuous shortening occurs. Immediately afterward, the cytoplasm moves toward and away from the bend. Thus the temporal sequence of events indicates that the shortening process at the bend is responsible for pulling the endoplasmic arm toward, and pushing the ectoplasmic arm away from, the bend.

In order to result in streaming, the contraction must remain localized in the vicinity of the bend. This can be accomplished only if the contraction is propagated posteriorly along the endoplasm of the intact cell (or endoplasmic arm of a streaming unit) at the same velocity as that at which the endoplasmic stream advances relative to the bend. Ordinarily, the contraction is inconspicuous because it remains at the bend. Occasionally, however, the contraction is seen to be propagated along straight sections of cytoplasm from one end of the capillary to the other. Occasionally also, the bend itself moves with the contraction, especially if the ectoplasmic arm is held in place. When this occurs, the bend is 'whipped' along the capillary by the propagated contraction.

A further manifestation of contractile activity is a 'twitching' movement which occurs just prior to cessation of streaming. Localized contractions may also give rise to very complicated rotatory and other movements.

There is evidence of a syneresis associated with the contraction at the fountain zone (stage I), or at the bends of cytoplasmic loops (stage II), which is probably analogous to hyaline cap formation in the intact cell. In the presence of traces of calcium ions, an increasing number of clear vacuoles forms after the membrane of the cell is ruptured. The vacuoles form as tiny tear-shaped bodies which suddenly 'blow up' like balloons in the fountain zone (stage I) or at the bend of a streaming unit (stage II). If the formation of these clear vacuoles is the result of syneresis, then the argument that hyaline cap formation results from syneresis associated from the fountain zone contraction is strengthened. It is then reasonable to suppose that this syneresis occurs also when insufficient calcium is present to cause the formation of a visible vacuolar membrane around the fluid expressed from the interstices of the contracting cytoplasm.

The streaming of amœba cytoplasm in the absence of the plasmalemma and ectoplasmic tube as structures completely eliminates the sol-gel or ectoplasmic contraction theory as a possible explanation for

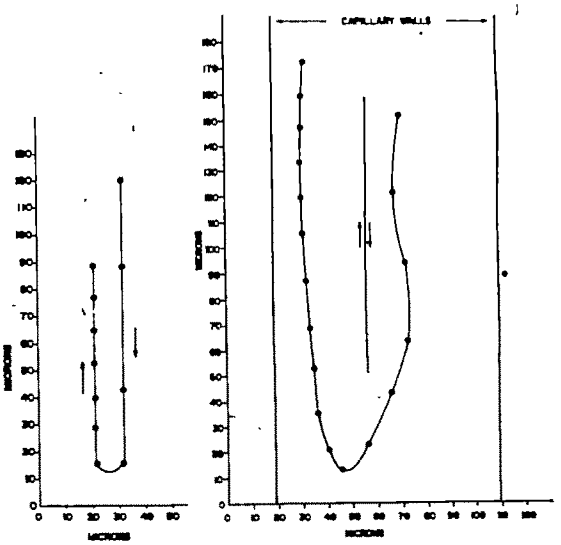

Fig. 4. Left: the positions occupied at intervals of 1 sec. by an inclusion as it moved forward in the endoplasm and backward in the ectoplasm relative to the tip of a pseudopod in an intact *Chaos chaos*. Right: the same for an inclusion carried in a U-shaped loop of dissociated cytoplasm. Note in both cases the retardation at the junction between the endoplasmic arm (streaming toward the bend) and the bend itself

streaming in cytoplasm dissociated from amœboid cells. This theory demands the presence of an intact ectoplasmic tube to convert ectoplasmic shortening into a pressure gradient.

The results of the present work provide additional evidence that the endoplasm of the amœba is not a structureless sol, but rather a material which is structurally and physiologically organized and capable of carrying on cytoplasmic streaming at the sub-cellular level. The partial disintegration of cytoplasm dissociated from giant amœbæ into motile 'units of streaming' provides evidence which is not only compatible with, but also provides further verification for, the fountain zone contraction theory of amœboid movement[4]. Each unit of streaming consists of a U-shaped loop or band of cytoplasm with a bend at which a contraction occurs. The two arms of the loop show a difference of consistency; the contracted or ectoplasmic arm is more rigid. Therefore, when the bend is held stationary and the contraction is propagated in one direction, the cytoplasm of the loop streams through the bend in the opposite direction.

We believe that the principle upon which the movement of amœba cytoplasm has been shown to depend may be widely applicable to many other cases of cytoplasmic streaming, and that the demonstration of this principle at the sub-cellular level represents an important step toward an understanding of the mechanism of amœboid movement and cytoplasmic streaming.

This investigation was supported by a Research Grant, C-3022, from the National Cancer Institute, National Institutes of Health, U.S. Public Health Service.

THE NATIONAL ENGINEERING LABORATORY, 1960

OPEN DAYS

THE third open days of the National Engineering Laboratory (formerly the Mechanical Engineering Research Laboratory), East Kilbride, Glasgow, held on June 15 and 16 and the evening of June 17, were attended by more than 2,200 representatives of industry, universities, technical colleges and other research organizations. All the work at East Kilbride and Thorntonhall was on display, and about a hundred items were specially featured. There was also a display describing the facilities available for carrying out sponsored investigations for individual firms.

The behaviour of metals under stress is the concern of the Materials Division, where the aim is to provide the designer with basic data on the strength of materials, particularly under fatigue and creep. In many components and structures, fatigue cracks can form very quickly, and it is necessary to know the conditions under which these will grow if the component is to be designed efficiently with economic use of material. Investigations, using 10-in. wide sheets under tensile fatigue loading, have shown that low stresses ($5 \pm 1\frac{1}{4}$ tons/in.^{2} for mild steel) are sufficient to cause cracks to grow, and this growth may be continuous or intermittent. When growth is continuous, for overall crack-lengths up to one-eighth of the total width of the sheet, the rate of growth is dependent on the cube of the alternating stress and on the current crack-length.

Fundamental studies of the mechanism of growth of fatigue cracks in mild steel indicate that the growing crack is made up of many small independent cracks which have no relation to the initial cracks found in brittle fracture or to the inclusion cavities of ductile fracture. It is thought that elementary fatigue cracks form as a result of the development of a sub-grain structure, the sub-grains being an essential feature of cyclic dislocation movement.

Under stress at high temperatures, materials undergo a slight continuous elongation, known as creep. To provide data for the adequate design of components which will operate under these conditions, as, for example, in steam-power plant, the Laboratory is examining the creep characteristics of typical engineering metallic alloys. Their properties, under simple and generalized loading conditions, under relaxation conditions where the total strain is kept constant, and under conditions leading to actual fracture, are being studied and the relation between creep-rate, stress and time has been established for several materials.

The development of techniques and apparatus for the accurate measurement of large water-flows in pipes is necessary for the efficient design and operation of hydraulic machinery. One technique employs propeller current meters, mounted in a predetermined pattern over the cross-section and each rotating at a speed proportional to the local velocity of flow. In conventional propeller meters, bearing friction at low flow-rates makes the meter calibration non-linear and dependent on time. The Fluids Division at the Laboratory has developed a frictionless meter incorporating a hydrostatic pressurized bearing which provides a dynamic film of water between rotating and fixed parts. Static friction is eliminated and linear calibration is now obtained over a wide range of flow-rates. It is hoped that precision moulding of the impeller will eliminate the need for calibration of individual meters when the first one or two impellers have been calibrated.

A robust dual-element thermometer has been devised to measure temperature between 0 and 50° C. to within a few millidegrees centigrade under industrial conditions. It is used in conjunction with an a.c. bridge having transformer ratio arms, and the circuit can be arranged to eliminate the effect of long supply leads and bridge outer leads. The temperature is obtained from the ratio of the temperature coefficients of resistance of the copper and minalpha elements, and the need for a highly stable external resistor (and consequent temperature-controlled enclosure) is eliminated.

Heat transfer is an essential process in the operation of a wide range of mechanical engineering equipment, and it is part of the concern of the Heat Division to obtain more accurate data for use in the design of such equipment. A particular example of fundamental importance in this field is the flow of heat between a pipe and a fluid passing through it. Studies of the effect of abrupt changes of section and right-angled bends in pipes have shown that for low flow-rates, and particularly for laminar flow, there is an increase in the heat-transfer coefficient after the discontinuity (in one instance the coefficient rose to ten times its normal value). This increase may extend up to 50 pipe diameters downstream of the discontinuity. For higher flow-rates, the increase in the heat-transfer coefficient is comparatively small and does not extend far along the pipe.

To enable heat-exchange apparatus to be designed more efficiently, there is need for a more accurate knowledge of the properties of the gases to be used, and the Division is producing tables of thermodynamic and transport properties of technically useful gases. The National Engineering Laboratory is the United Kingdom representative in the preparation of an internationally acceptable set of steam tables; a new skeleton table, extending up to 1,000 atmospheres and 800° C., is being drawn up. To reconcile the different experimental data and to keep them consistent with the thermodynamic relations, an equation of state, valid for the vapour state, has been devised, based on P-V-T data; this equation represents pressure as a double-power series in density and temperature, and all the other properties can be derived from it.

One of the aims of the Metrology Division is to improve the accuracy and performance of machine tools and mechanisms such as gears, lead screws, ball-bearings and universal joints; as part of the Division's work, new types of precision measuring instruments, using optical, mechanical, electronic and pneumatic techniques, are developed. Particular attention is being given to the application of moiré fringes to precision measurement, and automatic control of machine tools (moiré fringes are produced when light is shone through two similar gratings placed face to face with their lines not quite parallel). Using a photo-electric pick-up, linear or rotary movement can readily be converted into a corresponding electrical signal, and this system can be used as a basis for comparing the relative motion of two elements in a mechanism—the signal representing the error in relative motion can then be used to actuate a correction mechanism. A system of this type is now providing continuous and automatic correction of the errors in rotation of the worktable of a commercial gear-hobbing machine. A photographic process is used to produce the lines on the precision radial gratings for this and other applications; previously the lines were ruled on an aluminium-coated glass plate, using a circular dividing machine. A small segment of the grating is first ruled and is then mounted concentrically with a photographic plate secured to the table of the dividing machine. By alternate exposure of the plate to a beam of light passing through the master segment, and indexing of the table through an integral number of grating pitch spaces, a complete photographic copy is obtained. This method eliminates short-term periodic errors in the grating, and the time required for production can be reduced considerably (for a radial grating with 10,800 lines, from 4 days to about 3½ hr.).

Pressurized air bearings are being employed to reduce friction in instruments and machine tools. They can be used to provide a high-precision axis of rotation in journal bearings, or to enable a carriage to travel accurately in a straight line along a slideway. A typical application of the second type has been the development of a flat air bearing to support the ¼-ton worktable of a horizontal milling machine. Cutting performance of the machine is unimpaired, while it has been possible to reduce the size of the traverse motor from 2 to 1/50 h.p.

A clear understanding of the processes of lubrication and wear is essential if machines are to run efficiently and have a long service life. The Lubrication and Wear Division is studying one of the major forms of wear in machinery—the abrasive action of hard fine particles. This may occur, for example, in internal combustion engines, if the air is not properly filtered at intake, and in agricultural machinery, under the action of soil particles. Work on the resistance to abrasion of a wide range of carbon steels and cast irons has shown that in general an increase in hardness of the material improves the resistance, but in some cases other factors, such as graphite or eutectic cell-size in cast irons, may be equally or even more important. Other work has shown a correlation between resistance to abrasive wear and to fretting corrosion (the wear occurring between two contacting surfaces subject to repeated relative oscillatory motion), and it may ultimately become possible to predict fretting corrosion resistance from abrasive wear tests.

Under unsteady loads, such as are encountered in internal combustion engines and in high-speed turbo-machinery, the position of the shaft in a journal bearing varies in the bush, and excessive vibration and bearing failure may result. Inductive transducers are being used to detect and trace the shaft movement under the action of various loads, including a combined gravity load and unbalanced rotating load. The rupture of the lubricant film in the unloaded part and the consequent change in the hydrodynamic conditions in the bearing appear to be responsible for the observed variations in shaft movement.

The work of the Plasticity Division is directed towards obtaining a better understanding of the behaviour of metals during plastic deformation. This will lead to more effective utilization of metals, and in metal-working processes to improved techniques and more efficient machine tools.

In forming operations the temperature distribution within the metal must be known and controlled to avoid excessive rises of temperature which may cause undesirable changes in the properties of the product —for example, 'hot shortness' in extruded material. A combined theoretical and experimental technique is being used to determine the rates of rise of temperature in a material during extrusion, and a programme has been prepared for the Laboratory's *Deuce* computer to obtain the temperature distribution as a function of time under various extrusion conditions.

Investigations have shown that under high hydrostatic pressure, materials behave in a more ductile manner than at atmospheric pressure, and that some normally brittle materials, for example, bismuth and magnesium, can be successfully cold-extruded inside a chamber containing fluid at high pressure; a superimposed hydrostatic pressure of 2–3 tons/in.² may be sufficient to prevent cracking of the extruded product for low reductions in area. This technique may have several commercial applications, particularly in the working of new and difficult materials.

Apparatus to generate pressures up to 100,000 atmospheres in conjunction with temperatures up to 3,000° C. has also been built. This will be used to investigate the forming of new materials of technical and scientific interest under simultaneous high pressure and high temperature. Typical effects of such conditions are the transitions of graphite to diamond and hexagonal boron nitride to borazon. In the case of borazon, its great hardness and resistance to oxidation at high temperature give it considerable industrial potential.

R. I. LITHGOW

NEWS and VIEWS

Psychology at Leicester: Prof. S. G. McK. Lee

DR. S. G. McK. LEE, who has been elected to the new chair of psychology in the University of Leicester, is a South African by birth and gained his early education and teaching experience in psychology at the University College of Natal. His war service, during 1940–46, included four years as navigator with the South African Air Force and the Royal Air Force. Dr. Lee has a close knowledge of the language and culture of the Zulus, among whom he carried out studies in social psychology and cultural influences on personality. His reports on the 'crying hysteria' of Zulu women and the cultural significance given to their dreaming are well known. He has standardized intelligence tests and a version of the thematic apperception test for Africans. After taking his Ph.D. at Birkbeck College, London, where he also held a teaching post, Dr. Lee became in 1955 senior lecturer in psychology at the University College of Fort Hare, where, however, he reluctantly decided that political restrictions on African education would soon make his work nugatory. He returned to London, to join the staff of Bedford College, where he has taught for the past four years. In his recent research work he has brought together his training as an experimental psychologist and his experience in clinical psychology by investigating experimentally, in collaboration with Dr. D. W. Forrest, the effects of repressed interest and emotion on perception. He is now (in association with Dr. G. M. Carstairs, of the Medical Research Council) applying one of the experimental techniques developed for that purpose to a study of psychological aspects of hypertension.

C.S.I.R.O. Division of Physical Chemistry: Dr. S. D. Hamann

DR. S. D. HAMANN has been appointed chief of the Australian Commonwealth Scientific and Industrial Research Organization's Division of Physical Chemistry at Fishermen's Bend, Victoria. He succeeds Dr. K. L. Sutherland, who has resigned to become director of research for the Colonial Sugar Refining Co., Ltd. Dr. Hamann was born in Christchurch, New Zealand, in 1921. He graduated M.Sc. with honours at Canterbury College, having specialized in chemistry and physics. He spent more than four years in the Royal New Zealand Navy, being engaged almost continuously for three years in operational and technical research on radar. At the conclusion of the War, Dr. Hamann studied at the University of Manchester, and was awarded a Ph.D. degree in 1950. Having returned to Australia, he immediately joined the Commonwealth Scientific and Industrial Research Organization's High-Pressure Laboratory in the Chemical Engineering Department of the University of Sydney. He has been in charge of this Laboratory since 1952. Dr. Hamann has represented Australia at meetings of the International Union of Pure and Applied Chemistry in Zurich (1955) and Munich (1959).

C.S.I.R.O. Division of Forest Products: Mr. S. A. Clarke

MR. STANLEY A. CLARKE, chief of the Division of Forest Products of the Australian Commonwealth Scientific and Industrial Research Organization, retired from active duty on August 26. Born in Perth, Western Australia, in 1900, an engineering graduate of that State and an associate member of the Australian Institute of Engineers, Mr. Clarke has been associated with the Division of Forest Products since 1929. In that year he was seconded to the newly formed Division of Forest Products as officer-in-charge of seasoning and utilization. The following year he transferred to the permanent staff of the Division, and in 1931 was appointed as deputy chief of the Division. He held this position until 1944, when he succeeded the late Mr. I. H. Boas as chief of Division. Mr. Clarke has won the esteem and confidence of the Australian timber industry, and has established a reputation both in Australia and overseas for his ability to apply his engineering and scientific outlook to problems in the utilization of forest products. Devoting himself in the first instance to the problems of saw-milling, timber seasoning and timber grading, he afterwards became an authority on such widely diverse activities as those of the pulp and paper, fibre board and particle board industries. Since 1930 he has participated actively in the work of the Timber Industry Committee (formerly Timber Sectional Committee) of the Australian Standards Association, being appointed as chairman to the Committee in 1944. His advice has been widely sought by such countries as New Zealand, India and the United Kingdom. Mr. Clarke has taken a keen interest in the United Nations Food and Agriculture Organization's work in relation to forest products, and in addition to being chairman of the Asia–Pacific Regional Committee of Forest Products Research he is a permanent member of the Technical Panel on Wood Technology of the Organization.

Reflexion of Signals from *Echo* 1

A TEAM of scientists from the Post Office and the Royal Radar Establishment, Malvern, succeeded on the evening of August 29 in receiving signals at Malvern reflected from the Earth satellite *Echo* 1 (see *Nature*, August 27, p. 741). The signals, which included both unmodulated carrier waves and speech transmissions, were transmitted from the Bell Telephone Laboratories at New Jersey, U.S.A. Prof. A. C. B. Lovell, of the Jodrell Bank Radio Astronomy Station, announced that signals from New Jersey had been received about a week ago, using the 250-ft. radio telescope. The present tests at Malvern are of particular interest since the radio aerial used was only 20 ft. in diameter.

The National Chemical Laboratory

THE report of the National Chemical Laboratory, 1959 (London: H.M. Stationery Office, 1960. 4*s*. 6*d*. net), begins with a report of a steering committee set up in October 1958, which made several recommendations. Thus the Committee proposed the transference of the collection of industrial bacteria to the Torry Research Station and the disbanding of the research section. The greater proportion of the National Chemical Laboratory's effort is to be devoted to work on the thermodynamic properties of pure materials. Work on high polymers is reduced to the investigation of certain aspects. Work on selective membranes is to be continued. There will be closer co-operation with the National Physical Laboratory. The work on corrosion, always a valuable part of the research in the National Chemical Laboratory, is continuing. A Radio-Isotope Applications Group works at Harwell. The report as a whole contains some interesting material, usually presented in sufficient detail to be intelligible to non-specialists.

Science Horizons

COMMENCING with the August issue, the title of the monthly review of scientific progress in the United States of America, *Atoms for Peace Digest*, issued by the United States Information Service, American Embassy, London, W.1, has been changed to *Science Horizons*, to reflect the broadened editorial content of the journal. For some time now the journal has been reporting developments in space research, electronics and technology generally, in addition to specific developments in nucleonics, and these are now to become regular features. Topics discussed in the August issue include ram-jet engines for supersonic airliners; a world-wide, all-weather navigation system, based on Earth satellites; and the 'laser', a light amplifier. *Science Horizons* is to be published during the third week of every month, but will be dated a month ahead, that is, for example, the October issue will be distributed during the third week of September.

International Scientific Radio Union

THE thirteenth General Assembly of the International Scientific Radio Union (U.R.S.I.) is being held at University College, London, during September 5–15. The Union is in the nature of a federation of national scientific bodies interested in the radio aspects of scientific research and development. The present assembly is being held at the invitation of the Royal Society which, through its British National Committee for Scientific Radio, is responsible for making the arrangements for this meeting, under the chairmanship of Mr. J. A. Radcliffe. The previous General Assembly was held at Boulder, Colorado, in 1957 (see *Nature*, 181, 465; 1958), and Dr. L. V. Berkner, head of Associated Universities, Inc., New York, was elected president of the Union for the current term, and is presiding over the plenary meetings in London. The scientific programme of the forthcoming assembly is organized under seven commissions, the titles and chairmen of which are: I, Radio Measurements and Standards (Dr. B. Decaux); II, Radio and Troposphere (Dr. R. L. Smith-Rose); III, Ionospheric Radio (Dr. D. F. Martyn); IV, Radio Noise of Terrestrial Origin (Prof. R. A. Helliwell); V, Radio Astronomy (Prof. A. C. B. Lovell); VI, Radio Waves and Circuits (Prof. S. Silver); and VII, Radioelectronics (Prof. W. G. Shepherd).

The British Pteridological Society

DURING the latter half of the last century, searching for and growing wild varieties of British ferns were wide-spread pastimes. In 1891 a group of Lakeland hunters formed themselves into the Northern British Pteridological Society and attracted members from all over Britain. During those early years, the emphasis was on varieties and their cultivation, and this is still regarded as an important and integral part of the activities. In recent years, the scientific side has gradually developed and increased in importance. This movement has been greatly accelerated during the past year, which has seen big changes and re-organization in the Society. The importance of operating in a much wider field has been realized and the Society's aims now include the study of world ferns and fern allies. The recording and dissemination of information on the British Pteridophyta still remain, of course, a major activity. In addition, an attempt is being made to build up a herbarium of varieties in existence to-day. An annual excursion for a week to parts of the country where ferns abound has long been a popular institution in the Society. Additional meetings are held during the year to cater for members whose interests are taxonomic rather than horticultural. Day field meetings and indoor meetings are held in the London area, and a separate northern meetings secretary and committee organize field meetings for members in the north of England and in Scotland. The current annual subscription is 10*s*. Members receive the *British Fern Gazette*, published annually, and, occasionally, other publications. The secretary is Mr. J. W. Dyce, 46 Sedley Rise, Loughton, Essex.

Mushroom Growing

THE Ministry of Agriculture, Fisheries and Food is to be congratulated on the new edition of its bulletin on "Mushroom Growing" (Bull. No. 34, seventh ed., price 6*s*. H.M.S.O., London, 1960). The sixth edition was issued some six years ago, and, as noted in the foreword, both before then and since, the mushroom-growing industry has seen many important changes, specializations and refinements in its practices. Indeed, "Changes in practice are occurring so rapidly that no account can be reasonably up to date for very long". It is in the light of the many recent and contemporary changes and innovations that the present guide has been written under the chairmanship of Mr. F. W. Toovey, director of the Glasshouse Crops Research Institute. The essential facts and procedures are well and fully set out, and are illustrated by some excellent photographs.

Botanical Garden in Tashkent

A NEW botanical garden was founded in 1950 in Tashkent's northern suburb. Of the total projected area of 80 hectares, 40 hectares are now occupied by a dendro park containing 1,300 species of trees and shrubs belonging to the local, European, Far Eastern, Chinese and North American flora. The dendro park contains several artificial ponds and it is traversed by 12 km. of roads. As described by F. N. Rusanov (*Priroda*, 7, 61; 1959) the dendro park contains many well-acclimatized, rare and valuable plants and hybrids. The park is at the service of the whole of Central Asia.

Submarine Oil Drilling

According to M. K. Kalinko (*Priroda*, 11, 25; 1959), the first attempt to extract petroleum from rocks underlying the bottom of the Caspian Sea were made in the region near Baku in the beginning of the nineteenth century. The workings, protected by two wooden frames lowered at the bottom of the sea, were destroyed by a storm in 1825. In 1910, in an attempt to infill a shallow bay, petroleum was discovered, which led to drilling in the region; but planned survey and undersea petroleum extraction began only in 1935. At the present time, undersea extraction is carried out on a large scale in eight separate areas in the region of Baku, and in 1958 this work extended to the eastern part of the Caspian Sea. Outside Russia, the submarine extraction of petroleum began in Japan in 1888, but it reached its maximum development in the Gulf of Mexico, California, Venezuela, and the Persian Gulf. Special surveying and prospecting methods are now employed for the investigation of the possible offshore petroleum provinces or 'aquatories'. The author of this article gives a general survey of the world's offshore petroliferous provinces, which in his opinion may yield more petroleum than the overland provinces.

Use of Gamma-Radiation Sources for the Sterilization of Pharmaceutical Products

A report issued by the Association of the British Pharmaceutical Industry (B.M.A. House, Tavistock Square, London, W.C.1. Pp. 17) describes the findings of a working party set up by a number of pharmaceutical firms and other interested bodies, including the Atomic Energy Research Establishment, to investigate whether pharmaceutical products and containers could be usefully sterilized on a commercial scale by using gamma-radiation. The results of the tests are summarized in a convenient form in this report. A dose of $2{\cdot}5 \times 10^6$ rads (from cobalt-60) appeared to be adequate to achieve sterility, but it caused changes in many of the substances tested, and in many cases rendered them unsuitable for use. It is suggested that the method may be usefully applied in particular cases, but the results, in general, are not considered sufficiently encouraging to justify continuation of the present investigation on a group basis.

Molecular and Crystal Structure Models

A bibliography on molecular and crystal structure models used extensively in research and as teaching aids has recently been published (U.S. Department of Commerce: National Bureau of Standards. Monograph No. 14: Bibliography on Molecular and Crystal Structure Models. By Deane K. Smith. Pp. iv+7. Washington, D.C.: Government Printing Office, 1960. 15 cents). The references are grouped into four broad classifications—models in general, static models, dynamic models, and constructional devices—and the static model classification is, in addition, subdivided into closed molecular (Stuart type), closed packing, open molecular, open crystal structure, open with parallel rods, polyhedral, and miscellaneous models. The list of references is preceded by brief explanations of the various types of model which indicate the more significant articles relating to them.

Hæmatology of the Central Australian Aborigine

Various hæmatological observations on central Australian aborigines have been made by J. R. Casey-Smith, of the Department of Anatomy, University of Adelaide (*Austral. J. Exp. Biol. and Med. Sci.*). One group contained some thirty nomadic males living under primitive conditions for most of the year. The second group consisted of about twenty males and fifteen females living under urban conditions, on an almost European diet. The nomadic group's diet had a high iron content. The hæmoglobin-levels of a control group of Europeans in Central Australia were also measured. Hæmoglobin and hæmatocrit values of the nomads were higher than those of the 'urban' males; neither sex of the 'urban' community differed significantly from the European controls. The erythrocyte counts showed no significant difference between the two male groups. Hæmoglobin-levels of sixteen Europeans living at Alice Springs were almost the same as those of the 'urban' males. The mean corpuscular volumes and the mean corpuscular hæmoglobins of the nomads were just greater than those of the Europeans, but the 'urban' natives did not differ significantly from either the nomads or Europeans. The mean corpuscular hæmoglobin concentrations did not differ significantly between the groups or from European standards. Erythrocyte osmotic fragilities showed an increase in hæmolysis at 0·5 *N*, but otherwise were not significantly different from those of Europeans. The aborigines did not differ significantly among themselves. The erythrocyte sedimentation-rates were greater in all groups of aborigines when compared with Europeans, but the nomads' values were less than those of the urban groups.

Virus-Streak Disease of Tomatoes

The syndrome of the streak disease of tomatoes in Ontario has been shown to be double-virus in nature, resulting from the synergistic action of tobacco mosaic virus and potato virus *X* (MacNeill, B. H., and Ismen, Hikmet, *Canad. J. Bot.*, 38, 9; 1960). Expression of the disease was found to depend on both virus components of the complex, a variation in strain characteristics of either tobacco mosaic virus or potato virus *X* being reflected in the intensity of their interaction in the tomato. The extreme severity of streak in the greenhouse and field tomato crops in Ontario is associated with what appears to be a geographical strain of tobacco mosaic virus. This virus is characterized by the induction of primary local lesion in petunia without subsequent systemic invasion of that host. Air temperature profoundly affects the development of streak, symptoms being masked above the critical temperature of 26° C. This phenomenon is a true masking effect with both viruses becoming latent in the tomato host.

Excavation of La Grotte de Rochereil

It is a pleasure to direct attention to a straightforward cave excavation where the finds are of prime importance and are not dependent on a statistical or other theory which has to be demonstrated ("La Grotte de Rochereil", by P. E. Jude, *Mém.* 30, *Arch. Inst. Paléont. Humaine*. Masson et Cie., Paris).

The site is not far from Périgueux, and the cultures present are the late Magdalenian (mostly *M*6) and Azilian. The fauna indicates a very cold period during the Magdalenian occupation, succeeded by an unpleasant period of transition leading to a more temperate climate. The implements, both in flint and bone, are numerous and characteristic, and many of the bone tools are decorated. Human remains occur in each culture-level. A distribution map of Azilian finds in south-west France is given, and it would seem to rule out the theory that there was direct connexion between the Azilian of south-west France and the early Mesolithic cultures (Obanian, etc.) of Ireland and western Scotland, linked by a series of cultural sites now under the sea. Actually, Azilian sites are conspicuously absent from the coastal areas of south-west France. "La Grotte de Rochereil" is a worthy volume to add to the other *Mémoires* of the Institute of Human Palæontology; it is well illustrated.

Research on Tinplate in Australia

The Broken Hill Proprietary Company, the sole producer of tinplate in Australia, has made a grant of £6,000 per annum to support tinplate research in the Commonwealth Scientific and Industrial Research Organization. The grant will be used to support investigations at the Organization's Division of Food Preservation and Transport at Homebush, New South Wales; this is the main centre in Australia for research on tinplate packaging problems. One project to be undertaken will be a study of the reasons why certain foods sometimes cause intense corrosion or deep pitting of tinplate. Until 1957, when the Broken Hill Proprietary Company opened its new plant at Port Kembla, Australian supplies of tinplate were all imported; now, however, the Company supplies hot-dipped tinplate for the majority of the food cans manufactured in Australia, and it will be possible for research workers to trace the history of the plate right back to the steel ingot; this will be very useful in corrosion studies.

Physiological Role of Fast Transfer Reactions

To inquire into the possible physiological role of fast transfer reactions in eliciting specific interactions in ordered macromolecular structures, a series of seminar lectures was held at the Massachusetts Institute of Technology during the spring term of 1960. Included were lectures on electron and energy transfer mechanisms and on current concepts of proton transport mechanisms of immediate biophysical and biochemical significance. Properties of water and ice crucial for proton transfer were reviewed. Six lectures of a more general nature dealt with aspects of macromolecular interaction properties. Abstracts of these lectures and pertinent references are available free of charge. Requests should be sent to Prof. Francis O. Schmitt, Department of Biology, Massachusetts Institute of Technology, Cambridge 39, Mass.

Foundation of Plant Geography

Students of the history of botany will note with interest and appreciation the production of a facsimile edition of the essay by Alexander von Humboldt and A. Bonpland on the "Géographie des Plantes", dated Paris 1805, but believed not to have been issued until two years later. This work, the original of which is not readily accessible, has been issued by the Society for the Bibliography of Natural History, as Sherborn Fund Facsimile, No. 1 (c/o British Museum (Natural History), London, S.W.7; price 10*s*.). Humboldt is generally regarded as the founder of modern plant geography, and here, in the boldly printed pages of his "Essai", some of his original comprehensive observations and ideas are set out.

Society for Applied Bacteriology: Officers

At the annual meeting of the Society for Applied Bacteriology, the following officers were elected: *Hon. President*, Mr. G. Sykes; *Hon. Secretary*, Dr. Ella M. Barnes; *Hon. Treasurer*, Mr. G. Elis Jones; *Hon. Editors*, Dr. S. E. Jacobs and Dr. D. J. Jayne-Williams; *Hon. Publications Manager*, Mr. A. H. Walters; *Hon. Advertising Manager*, Mr. E. J. Mann; *Members of Committee*, Dr. Eve Billing, Mr. N. J. Butler, Mr. B. M. Gibbs, Dr. N. D. Harris, Dr. J. R. Norris, Dr. Jane Meiklejohn, Dr. A. M. Paton, Dr. Joan Taylor, Dr. G. C. Ware; (*ex-officio*), Dr. C. A. E. Briggs, Mr. D. A. McKenzie.

The Animal Health Trust: Educational Awards

The following Animal Health Trust educational awards for 1960–61 have been announced: *Wellcome Fellowships*: R. B. Taylor (University of Liverpool), to undertake research into tolerance and the development of immunity in animals at the Department of Zoology, Cambridge; I. J. F. Stobo (University of Edinburgh), to study problems of the early weaned calf, with particular reference to nutrition and the development of the digestive organs, at the National Institute for Research in Dairying, Shinfield, Reading. *Research Training Scholarships*: R.A.S.E. Research Training Scholarship to R. M. Connan, of the Royal Veterinary College, to study general pathology at the Department of Animal Pathology, Cambridge; A. D. Allen Memorial Scholarship to G. W. Osbaldiston, of the University of Queensland, to study animal nutrition and general husbandry at Cambridge; Dr. W. N. M. Foster, of the University of Edinburgh, to undertake research into the problem of 'quidding' in Border Leicester sheep and to complete his veterinary degree at the Royal (Dick) School of Veterinary Studies, Edinburgh; R. M. Griffin, of the Federal Department of Veterinary Research, Northern Nigeria, to continue investigations into contagious bovine pleuropneumonia and to attend the course for the diploma of bacteriology at the London School of Hygiene and Tropical Medicine; I. F. H. Purchase, of the University of Pretoria, for work in the field of animal anæsthesia at Cambridge.

University News: London

Mr. G. Belyavin, senior lecturer at University College Hospital Medical School, has been appointed to the University chair of bacteriology tenable at that School.

Mr. E. J. Ambrose, senior lecturer at the Institute of Cancer Research: Royal Cancer Hospital, has been appointed to the University readership in physical chemistry tenable at that Institute. Dr. F. A. Holton, a member of the scientific staff of the Experimental Radiopathology Research Unit of the Medical Research Council at Hammersmith Hospital, has been appointed to the University readership in veterinary biochemistry tenable at the Royal Veterinary College.

The title of reader in chemistry has been conferred on Mr. G. M. Timmis in respect of his post at the Institute of Cancer Research: Royal Cancer Hospital; and that of reader in mechanical engineering on Dr. C. R. Webb in respect of his post at Queen Mary College.

Pittsburgh

The following appointments have been announced: Dr. Theodore Holstein, to be professor of physics; Dr. Robert L. Wolke, to be associate professor of chemistry; Dr. David S. Feingold, to be assistant professor of bacteriology; and Dr. Robert Silverman, to be assistant professor of mathematics.

Announcements

Dr. Maurice Ewing, director of the Lamont Geological Observatory at Columbia University, has been awarded the John Fleming Medal of the American Institute of Geonomy and Natural Resources.

Mr. F. E. Shotton, deputy county advisory officer, Norfolk, in the National Agricultural Advisory Service, has been appointed director of Terrington and Kirton Experimental Husbandry Farms, Terrington St. Clement, King's Lynn, Norfolk, in succession to Mr. A. C. Owers, who is resigning on November 1.

Dr. W. M. Hampton is retiring this month from the position of managing director of Chance Brothers Ltd., Glass Works, Smethwick, Birmingham, after 43 years with the company. He joined the firm as a chemist in the then newly formed research laboratories, and has been successively manager of the Optical Glass Department, director of research, technical director, 1940, and managing director, 1953. Dr. Hampton will remain a member of the Chance Brothers board.

Dr. N. E. Odell, of Clare College, Cambridge, has been appointed by the South East Asia Treaty Organization to the chair of geology in the University of Peshawar, which is tenable for a year or more.

Dr. John D. Kendall has been appointed director of European research laboratories to be established by the Minnesota Mining and Manufacturing Co., Ltd. Dr. Kendall, who is a graduate of the Imperial College of Science and Technology, London, has been responsible for many years for the direction of organic chemical research at Ilford, Ltd., and is known for his work on photographic sensitizing dyes and developers.

A symposium on "Flow Measurement in Closed Conduits" will be held at the National Engineering Laboratory, East Kilbride, Glasgow, during September 27–30. Attendance is by invitation.

The first International Congress of Food Science and Technology will be held in London during September 18–21, 1962, under the presidency of Lord Rank. Further information can be obtained from Col. Francis J. Griffin, 14 Belgrave Square, London, S.W.1.

The Nutrition Society (Scottish Group) is to hold a symposium on "Food Habits in Britain" at the Institute of Physiology, University of Glasgow, on September 24. Further information can be obtained from Dr. J. Davidson, Rowett Research Institute, Bucksburn, Aberdeen.

A postgraduate course on "Recent Advances in Steroid Chemistry" is being organized by the Kingston Technical College. There will be eleven weekly evening lectures by distinguished visitors commencing on September 28. Further information can be obtained from N. Lindop, Department of Chemistry, Biology and Geology, Kingston Technical College, Fassett Road, Kingston-upon-Thames.

Prof. W. T. Astbury, professor of biomolecular physics in the University of Leeds, will deliver the ninth Procter Memorial Lecture of the Society of Leather Trades Chemists at Leeds on September 23. The annual meeting of the Society is being held in the University of Leeds during September 23 and 24.

The Institute of Physics and the Physical Society is arranging a conference on "Diamond Physics", to be held at the J. J. Thomson Physical Laboratory, University of Reading, during September 22–23. During the meeting Prof. R. V. Jones will deliver the Duddell Medal address; he will speak on "Some Developments of the Optical Lever".

An informal discussion on the "Ultracentrifugation of Biological Macromolecules", organized on behalf of the Colloid and Biophysics Committee of the Faraday Society, will be held at the Medical School, University of Birmingham, during September 14–15. Details can be obtained from Dr. D. R. Stanworth, Department of Experimental Pathology, Medical School, Birmingham 15.

A four-day course for trade union officials on "The Industrial Uses of Radioisotopes" is to be held at the United Kingdom Atomic Energy Authority's Isotope School, Wantage, Berks, during September 20–23. Provision is also being made to accommodate students. Further information can be obtained from the General Secretary, Trade Union Congress, Congress House, Great Russell Street, London, W.C.1.

The first joint symposium, under the auspices of the Internation Union of Biochemistry and the International Union of Biological Sciences, has been organized by Profs. O. Lindberg and T. W. Goodwin and will be held at the Wenner-Grens Institut, Stockholm, during September 12–17. The subject will be "Biological Structure and Function". Further information can be obtained from Prof. T. W. Goodwin, Department of Agricultural Biochemistry, University College of Wales, Aberystwyth.

A new approach to training senior scientists and technologists in administration, based on case studies, has been developed at the Northampton College of Advanced Technology, London. This serves as a basis of the advanced course on "Direction and Supervision of Scientific and Engineering Personnel", which will begin on October 12 and will consist of meetings at fortnightly intervals, for a whole day at a time, until June 7, 1961. The organizers and tutors are Mr. A. C. Leyton, Mr. Z. M. T. Tarkowski and Miss Avice V. Turnbull. Further information can be obtained from Mr. Z. M. T. Tarkowski, 703 Frobisher House, Dolphin Square, London, S.W.1.

Erratum. In the obituary notice of Prof. Max von Laue in *Nature* of August 27, p. 738, a misunderstanding led to an alteration being made in the reference to von Laue's obituary of Haber. The full quotation is: "Themistokles ist in die Geschichte eingegangen nicht als der Verbannte am Hof des Perserkonigs, sondern als der Sieger von Salamis. Haber wird in die Geschichte eingehen als der geniale Erfinder desjenigen Verfahrens, Stickstoff mit Wasserstoff zu verbinden . . ." (*Naturwiss.*, **22**, 97; 1934).

BRITISH COLONIAL TERRITORIES

"THE Colonial Territories, 1959–1960", while still providing the convenient compendium of information to such publications as "Colonial Research", is of slighter interest to the scientist and technologist than previous issues (pp. vi+147. Cmnd. 1065. London: H.M. Stationery Office, 1960. 6s. 6d. net). The section, "Research and Surveys", has been omitted and also that dealing with international relations, and information on the latter topic is now scattered through the other chapters. Recruitment to the public service in overseas territories through the Colonial Office decreased during the year: 1,083 appointments were made as against 1,335 in 1958, and of these, 250 were teachers, 48 agricultural officers, 93 engineers and 100 doctors. Vacancies at the end of the year totalled 866, compared with 964 at the end of 1958. Training courses and attachments were arranged for 2,239 officers of overseas governments, a decrease of 196. Expenditure on development and welfare schemes and on research was about £24·4 million, and the estimated cost of approved technical assistance projects in British dependent territories in 1960 under the United Nations Expanded Programme of Technical Assistance is 1·1 million dollars compared with 1·06 million dollars in 1959. Under this programme 120 experts and 20 fellowship holders were provided, of whom 71 experts and 1 fellowship holder were provided by the World Health Organization, 23 experts and 11 fellowship holders by the Food and Agriculture Organization, 9 experts and 4 fellowship holders by the Bureau of Technical Assistance, and 6 experts and 1 fellowship holder by the United Nations Educational, Scientific and Cultural Organization. On March 31 some 30 specialists from the United States were serving in the African territories, and the United Nations Special Fund has approved grants of 700,000 dollars for a survey of a multi-purpose dam site on the Niger River, 850,000 dollars for the engineering faculty of the University College of the West Indies and 250,000 dollars for a survey of siltation conditions of Demerara River, British Guiana.

The number of students at the universities and university colleges, apart from the 330 at the University College of Sierra Leone, which was not included last year, increased by 385, and of the total 213 are at the Royal University of Malta, 1,268 at the University of Hong Kong, 695 at the University College of the West Indies, 1,112 at the University College, Ibadan, and 880 at the University College of East Africa. The Royal Technical College of East Africa admitted 288 students, and there are more than 1,000 students at the Nigerian College of Arts, Science and Technology. Under the Fulbright agreement, nine American teachers were attached to schools in British Guiana, Malta, Western Nigeria, Northern Rhodesia, Uganda, Zanzibar and the West Indies, two senior American research workers were attached to university and research institutions in Kenya and Northern Rhodesia, and one scientist continued work on the preservation of wild life in Uganda. Fulbright travel grants enabled lecturers from University College, Ibadan, and the University College of East Africa, and a graduate from Kenya to visit the United States for research and lecturing, and sixteen students from Cyprus, Malta, Jamaica, Hong Kong, Kenya, Nigeria, Tanganyika and Uganda were awarded grants for one year of study in the United States. The use of the services of the Overseas Visual Aids Centre has grown rapidly.

Under medical and health services the report records a localized outbreak of 117 cases of typhoid fever in North Borneo, but otherwise the incidence of communicable disease fell, though in an outbreak of cerebro-spinal meningitis in Northern Nigeria there were 1,450 deaths. Major schemes for the complete eradication of malaria continued, and extended trials of recent drugs for treatment of leprosy continued in Nigeria, Kenya, Uganda and elsewhere. Studies of acute anterior poliomyelitis have indicated a very high degree of natural immunity among the locally born population of the Seychelles and St. Lucia. Mass campaigns against yaws using penicillin have been strikingly successful, but despite intensive and persistent attempts to maintain safe vaccination-rates, smallpox remains endemic in Africa.

SCIENCE AND EDUCATION IN BRITAIN

TWO short but interesting debates on science and education were held in the House of Commons on July 27. The first of these, arising out of a prayer to withhold assent to University Court Ordinance No. 350 (Universities of St. Andrews, Glasgow, Aberdeen and Edinburgh) governing regulations for research students and the appointment of research Fellows, related to the part of the universities of Scotland in the revival and stimulation of industrial activity. Mr. A. Woodburn, who moved the prayer, questioned whether they are doing enough and quoted opinion that neither Scottish industry nor the Scottish universities had quite come to terms with this age of science and technology. While 17 per cent of students in Scotland took a first degree in science, for science and technology the figure was only 11 per cent, and research students in science and technology were only 8 per cent of those in Great Britain, and only 10 out of 17 Department of Scientific and Industrial Research awards to advanced course students were taken up in 1960 compared with 251 out of 344 in the United Kingdom, and grants in support of special researches at Scottish universities, while amounting to £267,000, were only 7 per cent of the total for Great Britain. This latter figure was attributed to the lack of applications and proposals, and not to any restrictions on the part of the Department. Mr. Woodburn also remarked that only 2·7 per cent of research and development in private industry proceeds in Scotland, and that the Department of Scientific and Industrial Research is responsible for 81 per cent of research in shipbuilding and engineering. Some 58 per cent of engineering students in the University of Glasgow found work out of Scotland; for Edinburgh the figure was 69 per cent, and for Aberdeen 64 per cent.

Lady Tweedsmuir, who supported the Ordinance, asked for more information about university expenditure on research and on teaching. At Aberdeen in 1959–60 there were 91 full-time and 24 part-time postgraduate research students, compared with 77 and 22, respectively, in 1954–55. Research Fellows were very few, and the Scottish universities asked of this Ordinance that they should have the same facilities as English universities enjoyed to attract research workers. Mr. G. M. Thomson, who also asked for further information, questioned whether the pattern of professorships in the Scottish universities is appropriate to modern needs. He also stressed the importance of adequate finance, and suggested that more provision is required for the training of postgraduate students, better facilities for those with a technological qualification to qualify for research awards and a free flow of information between the universities, Parliament and the interested public. Sir Myer Galpern challenged some of these views, and suggested that much information is already available; he claimed that the Scottish universities already produce research students of very high calibre. The Joint Under-Secretary of State for Scotland, Mr. Niall Macpherson, intervened to point out that the Government regards the matter as one for the universities alone, and stressed its desire not to infringe their independence in matters of academic policy. Miss M. Herbison, referring to applications for grants for special researches from the Department of Scientific and Industrial Research, pointed out that of 25 in 1959–60 from Scottish universities, 13 came from the Royal College of Science and Technology, Glasgow. Dr. A. E. Thompson also supported this plea for more co-operation between the universities and the technical colleges, and for much greater facilities for exchange of staff between universities and other research institutions.

Another debate, on an adjournment, was opened by Mr. T. F. Peart, who raised specifically the responsibilities of the Minister for Science and his relation to the Ministry of Education. After stressing the importance of the contribution which British scientific man-power should make to Colonial development, Mr. Peart urged the full implementation of the De La Warr report on higher education in agriculture, stressed the need for adequate teaching of science in the teacher-training colleges and for a good supply of graduates in science from the universities who would take a teacher's diploma. He said he is concerned about the teaching of science in girls' schools and the supply of science teachers and equipment for such schools, and asked for a major debate on the place of science in our economy and the functions and responsibilities of the Minister for Science and the Minister of Education. The Parliamentary Secretary to the Minister of Education, Mr. K. Thompson, replying for the Government, welcomed the debate, but claimed that much is already being done to relieve the shortage of science teachers. He said that a very large proportion of the expansion of the teacher-training colleges would be in the numbers of teachers qualified to teach science at various levels in the schools. He agreed that we could also use part of this expanded output to provide an introduction to science in the primary as well as secondary modern and grammar schools. In the main, there are, he said, three levels of teacher-training for science courses in the training colleges: the ordinary curriculum; one providing for a main study of a science subject; and the advanced specialist course in a science subject. The number of teacher-training college students in mathematics and science has increased from 600 in 1956–57 to more than 1,100 in 1959–60, and the net increase in mathematics and science graduates in 1959 was 612. Plans for university expansion should provide an 80 per cent increase in science graduates in the period up to 1960.

ADULT EDUCATION

A HEARTWARMING tribute to the work of local enthusiasts for continued education has been paid by the Joint Committee for Adult Education of Queen's University of Belfast. In its twenty-eighth annual report it states that "it is commonplace, when adult education is discussed to-day, to lament the crusades of the founding fathers. It is even commoner to deprecate the decline of local responsibility and initiative, and the abdication of sustained and particular studies, in favour of the armchair and the printed or televised magazine. The experience of the Joint Committee and its officers is in contrast to all this".

These words, to the University Council for Adult Education, are in general borne out by the reports of other extra-mural departments*.

In spite of problems of finance, the total number of courses shows a slight increase, from 4,612 in 1957–58 to 4,741 in 1958–59. The volume of work has remained almost stationary for the past three years, but these figures mask the continued decline of tutorial classes, a trend which has gone on steadily for several years, as is shown by the figures:

1954–55	1955–56	1956–57	1957–58	1958–59
963	959	950	904	851

Its decline must cause disquiet, but it is encouraging that tutorial classes organized in collaboration with the Workers' Educational Association have shown a less-sharp fall (from 619 to 600) than others (from 285 to 241).

Television has been regarded as a serious rival to adult education, and blamed for the decline in tutorial classes. It is therefore interesting to find the University College of North Wales, Bangor, postulating the possibility that the coming of television may prove an advantage to adult education in so far as its better programmes tend to encourage "viewers to seek further enlightenment on the topics treated in them while the inferior programmes drive the more intelligent citizen to seek better pastures".

---

* Universities Council for Adult Education. Report on the Year 1958–1959. Pp. 34. (Bristol: W. E. Salt, Honorary Secretary and Treasurer, The University, 1960.)

The number of residential courses shows a 12 per cent increase over the 1957–58 figure, although, as last year's total was smaller than the 1955–56 and 1956–57 figures, the gain in part represents a recovery in lost ground. The increase is entirely in the shorter residential courses, that is, those of not more than seven days in length. At Cambridge, where Madingley Hall has been used to the full extent of its availability, the most interesting and promising developments are thought to be those in residential courses.

Table 1. TRENDS IN ADULT EDUCATION, 1953–59

	1953–54	1954–55	1955–56	1956–57	1957–58	1958–59
Religion	180	211	222	252	251	270
Biology	245	258	252	274	274	294
Language and literature	636	685	675	681	689	719
Visual arts	—	—	—	370	383	421

Table 1 confirms certain trends which have become discernible in adult education during the past few years. The reasons for these changes are not clear, but speculation indicates that the hydrogen bomb and affairs in Africa throw up moral problems that turn the minds of some men and women to a deeper study of the religious beliefs which have been a formative force in Western civilization. The Dead Sea scrolls combine the excitement of archæological discovery with the higher criticism. The contraction of the world prompts the serious and sympathetic study of religions that become less strange the more they are understood. It is possible that courses with a religious content satisfy some of the interests that previously found an outlet in the study of philosophy and of international affairs. The upward trend of courses in the visual arts has become clearly discernible.

There has been a marked improvement during the past few years in much of the accommodation in which extra-mural work takes place. Gradually, it is being recognized that adult education needs, and deserves, accommodation of its own, and the number of adult education centres steadily increases, some provided by universities, some by local education authorities, and some by voluntary organizations. The University of Leeds has established non-residential centres for extra-mural work at Bradford and Middlesbrough, each under the oversight of a member of the Department's teaching staff acting as warden. The University of Liverpool has made the Royal Institution available as a centre for extra-mural courses.

The tendency towards meeting the needs of special groups is discernible in the class programme of extra-mural departments, as well as in residential courses. The Edinburgh report contains an apposite comment on this development: "There is a considerable demand for classes of a semi-vocational nature but in this field extra-mural educational activities are limited to work for which the university is particularly suited. Classes in Agricultural Law, Income Tax, Estate Duty and Company Administration, Industrial Law, Advanced Management, Effective Reading and Programming for Digital Computers indicate a change in the pattern of extra-mural work but they should be regarded as a widening of the scope of such work rather than a change of emphasis". Oxford has embarked on a scheme, with support from the Leverhulme Trust, for the preparation of relevant and conveniently accessible teaching material—hitherto lacking—in trade union education. Special studies are being undertaken in three industries in Oxford's area—coal mining, engineering, and road passenger transport—in the hope that the resulting material will be suitable for publication for use by classes throughout Great Britain.

THE MELLON INSTITUTE

THE annual report on research, by the chairman, Mr. M. B. Ridgway, to the Board of Trustees of the Mellon Institute for the year ended February 29, besides a review of activities and of independent research during the year, of the research services and research for public welfare, includes a list of research personnel and of publications of Mellon Institute members during the year*. Fundamental research now represents about 20 per cent of the Institute's research effort, and two new fundamental research groups, one in continuum mechanics and visco-elasticity and the other in theoretical chemistry, began activity during the year. Among the continuing groups, expansion was chiefly in polymer science, metal physics and radiation, while in the applied research groups those in the science of metals also expanded. The independent research staff increased from 56 to 77, and 16 groups are now engaged in fundamental research. At the end of the year there were 42 industrially sponsored fellowships and projects in applied science with a staff of 210. Research services employed 26 professional scientists, and exclusive of part-time employees the total staff of the Institute was 536; expenditure for fundamental and applied research during the year was 5,781,000 dollars.

In studies on enzymatic hydroxylation a third hydroxylating co-factor has now been isolated from cultures of *Mycobacterium* 607 which reverses the inhibition of hydroxylation caused by tetracycline and also that caused by 2:4-dinitrophenol. In inorganic chemistry osmium and ruthenium complexes were characterized and investigations started on the co-ordination complexes of rhenium, iridium and platinum, while many basic compounds have been prepared in polycrystalline form by homogeneous hydrolysis in the range 170–300° C. Investigations of the structure and properties of macromolecules continued, and the stress–strain curves for a wide variety of cross-linked polymers revealed substantial agreement with the theoretically predicted form when measurements were made under conditions permitting reasonable approach to equilibrium. In metal physics an improved method was developed for evaluating the lattice spacings of gold-based and silver-based alloys, and the study of strain-induced transformation in silver–zinc alloys in the β-phase range was completed, using metallographic and X-ray procedures. In organic chemistry, triphenyl-, trimethyl- and tributyl-phosphonium-fluorenylides, as well as triphenylarsoniumfluorenylide and dimethylsulphoniumfluorenylide were prepared and their properties and reactions studied, as well as the protonation of weak bases by sulphonic acid type of ion-exchange, while in physical chemistry exciton theory was applied to the vibrational spectra of molecular crystals, and the atomic co-ordinates and anisotropic thermal vibration parameters of α-quartz at room temperatures were precisely determined with accurate X-ray intensities from an almost ideally imperfect single crystal.

* Mellon Institute Research 1959–1960: The Annual Report of the Chairman, Matthew B. Ridgway, to the Board of Trustees of the Institute for the Fiscal Year ended February 29, 1960. Pp. vi+88. (Pittsburgh: Mellon Institute, 1960.)

Other work on the science of metals included the study of the solubility of nitrogen in the iron–manganese system, basic high-temperature strengthening mechanisms for ferrous alloys, the evolution of new ultra-high strength steels with a total alloy content not exceeding 9 per cent and the research and development of solid state devices for power utilization. Research for public welfare ranged over such fields as air purification, the protection of artists' materials from discoloration and deterioration, treatment of effluents, industrial hygiene, abatement of water pollution and examination of the toxicology of new organic chemicals. Among general research fellowships and projects may be mentioned those concerned with the development of new solid catalysts and the improvement of existing granular absorbents from bone products, the fundamental properties of porcelain-enamel glasses, computer components, special films and film-forming starch products, determination of the critical requirements for the ideal industrial felt fabric, the synthesis of new insecticides of the methylenedioxyphenyl group for use in combination with pyrethrins, the synthesis and evaluation of textile resins and softeners and the synthesis of lubricants and hydraulic fluids with improved stability to oxidation and heat. Chemical work on the genesis of petroleum continued, thermal degradation studies of the polyene pigments were initiated and work continued on the preparation and properties of novel types of silicone polymers and co-polymers, on organo-functional silicone chemistry and studies of the structure and properties of organosilicone compounds.

THE NATIONAL INSTITUTE FOR RESEARCH IN DAIRYING

In an official Government publication of a generation ago dairy research was defined as "the study by scientific methods of the dairy industry and its products, and of the fundamental principles underlying its operations". It is now almost fifty years since the National Institute for Research in Dairying was founded at Reading, and its annual report for 1959* illustrates how thoroughly that conception of the all-embracing nature of dairy research has been developed at what has undoubtedly become one of the most famous research stations in the world.

The dairy industry begins at the farm with the management of grassland and the production of feeding-stuffs for milk production, with the breeding, management, nutrition and health of the dairy stock and with the actual production and handling of the milk itself. When the milk leaves the farm, other important sections of the dairy industry are concerned with its transport and distribution, its manufacture into dairy products and with the engineering and machinery required for these purposes ; of course, the dairy industry in all its branches is concerned that milk and the products made from it should be bacteriologically sound and of the highest possible nutritive value. In all this there is immense scope for scientific research, both fundamental and applied, and at the National Institute, where there is now a total staff of about 370, of whom 114 are scientific or experimental officers : the three principal departments which deal mainly with milk production problems are the Dairy Husbandry, Feeding and Metabolism and Physiology Departments. The remaining seven principal Departments — Bacteriology, Chemical Microbiology, Chemistry, Physics, Radiobiochemistry, Nutrition and Engineering—are concerned partly with milk production and partly with the quality and handling of milk and with the nature and properties of milk products and the scientific principles underlying their manufacture. The main part of the report, occupying about 100 pages, gives an account of the work of each of these ten Departments and also of the Statistics Section and the Experimental Dairy, but for those who prefer to see at a glance what an important contribution to knowledge the Institute makes even in the relatively short period covered by this report, a brief outline is given of some of the most recent research findings. This outline occupies only three pages, but it includes some 23 separate items ranging from subjects such as haymaking with a forage harvester, rumen development in calves and work on teat-cup liners of various different designs, to the part played by certain hormones in lactation, the ultra-high-temperature sterilization of milk and problems associated with the manufacture of Cheddar cheese.

The research of a basic nature includes work in which radioactive isotopes have been used to investigate some of the enzyme mechanisms in the mammary gland mitochondria and also to obtain information on the proportions in which various lower fatty acids are formed from hemicellulose and α-cellulose in the rumen. It includes also the establishment of an infusion technique whereby solutions of lower fatty acids can be introduced into the rumen continuously for long periods and relationships worked out between the amounts and nature of the fatty acids in the rumen and the yield and composition of the milk. In research of a more applied nature, studies have been made of matters such as the circulation-cleaning of pipe-line recorder milking equipment and the development of a rapid method of determining lactose in separated milk and condensed whey which depends on infra-red absorption. Studies have been made also of the effect of mastitis on the yield and composition of milk.

---

* University of Reading. Report of the National Institute for Research in Dairying, 1959. Pp. 154. (Shinfield, Reading: National Institute for Research in Dairying, The University, Reading, 1960.) 4s.

Towards the end of the report a list is given of nearly 200 papers published by members of the staff during October 1958–September 1959. In the notes which deal with staff matters, reference is made to the fact that in 1959 Prof. R. G. Baskett took up his appointment as director of the Institute, and a brief but well-deserved reference is made to the retirement of Dr. A. T. R. Mattick, who has served the Institute and the dairy industry with distinction for some forty years.

J. A. B. SMITH

NEW AMERICAN OBSERVATORIES

IN order to make astronomical research facilities available to those many universities which cannot themselves afford the necessary expensive equipment, the National Science Foundation is providing financial support for the construction of two major observatories, the National Radio Astronomy Observatory at Green Bank, and the Kitt Peak National Observatory near Tucson, Arizona.

Green Bank, in Deer Creek Valley, West Virginia, is at an elevation of 2,600 ft., ringed by mountains rising to 4,000 ft., effectively shielding the site from man-made radio noise. The climate is mild, and there are no high winds which would make operation of a large radio telescope difficult. An 85-ft. telescope was brought into operation in October 1958, and since then construction of a 140-ft. telescope, laboratories, residences and workshops has been under way. The reflecting surface of the 85-ft. telescope, made of aluminium sheet, is accurate to ¼ in. and operates down to wave-lengths as short as 3·5 cm., at which the telescope beam width is 7 min. of arc. Both telescopes are on equatorial mountings. The moving mass of the 140-ft. telescope will exceed 2,000 tons, yet it will be capable of being steered with a precision of a fraction of a minute of arc and will also have a surface accurate to ¼ in. In addition to other small telescopes there is a horn 120 ft. long; the energy which this collects can be calculated from its dimensions and it is fixed so that it can observe the radio source in Cassiopeia each day, thus providing a standard calibration source in the sky available to many radio astronomers. A variety of receivers covering the wave-length range of 3·75–75 cm. is available, and three separate receivers working on different wave-lengths can be used simultaneously on the 85-ft. telescope. Besides being displayed on the chart of a pen recorder, the receiver outputs are digitized together with telescope position and time. Extensive use of digital computer techniques is already being made in analysing and reducing the observations.

Among the first observations made at the National Radio Astronomy Observatory were a study of the radio emissions from Jupiter and a survey of the central regions of the Galaxy at a wave-length of 3·75 cm. showing remarkable detailed structure. In addition, studies are being made of planetary nebulæ and ionized hydrogen clouds, supernovæ remnants and peculiar galaxies.

Three years were devoted to testing the seeing conditions at a number of places before Kitt Peak was chosen as the site for the National Observatory in March 1958. An agreement with the Papagos Indians (who call astronomers "the People with the Long Eyes") leased 200 acres to the Observatory, and construction of an 80-in. telescope is under way. This will have a coudé focus as well as prime and cassegrain, and will be equipped for direct photography, photoelectric photometry and spectroscopy. There is also a 36-in. telescope with a cassegrain spectrograph, and two 16-in. telescopes which will be used for bright star work. The University of Arizona is also moving a 36-in. telescope to the site.

On Kitt Peak there will be an optical workshop with some of the best testing facilities in the world, together with an office and laboratory building, dining hall and dormitory, houses and a shop. But the headquarters are adjacent to the University of Arizona in Tucson, and the staff and visiting astronomers will spend most of their time in the research offices there.

It has recently been decided to build a large solar telescope on Kitt Peak. The heliostat will have an 80-in. plane mirror feeding a 60-in., 300-ft. focal length concave mirror at the bottom of a tunnel 500 ft. long. The image of the Sun, 34 in. in diameter, will be reflected on to the slit of a large vacuum spectrograph. The outside of the building will be maintained at ambient temperature to prevent disturbing convection currents.

The National Observatory and the National Radio Astronomy Observatory will be valuable additions to the research facilities of universities which could not, alone, have provided them.

V. C. REDDISH

BIOLOGICAL EFFECTS OF EXPOSURE TO INTENSE RADIATION

A UNIQUE and important experiment to determine the biological effects of acute and high-level radiation exposure has recently been completed under the auspices of the International Atomic Energy Agency at the Boris Kidrich Institute at Vinca, near Belgrade, Yugoslavia. Details of the experiment were given at a press conference held at Vinca on April 27 by the international team of scientists responsible for its organization and execution, and a brief report of the experiment and the conference is published in the *International Atomic Energy Agency Bulletin*, 2, No. 3, 3 (July 1960).

It will be recalled that on October 15, 1958, during an accident to the nuclear reactor *RB* at the Institute, six persons in the immediate vicinity of the unshielded reactor were subjected to high doses of neutron- and gamma-radiation, and two others, farther away, received radiation doses in excess of the permissible level. After first-aid treatment at the Institute, they were transferred to the Centre for Professional Diseases in Belgrade. The six heavily irradiated patients were flown the following day to the Curie Hospital in Paris to receive special treatment by Dr. H. Jammet. One of the patients was cured by conventional treatment, including blood transfusions; but the other five, who had had blood-forming tissues in their bone marrow destroyed by the radiation, were given treatment involving the grafting of healthy bone marrow obtained from donors matched as closely as possible with the patients by detailed blood tests. This method of treatment had been tried before on an experimental basis but had not proved particularly successful. One of the five, presumably the one who had received the highest radiation dose, died before the treatment could take effect. The four others were gradually but successfully cured. A full report of the treatment has not yet been published. The success, however, represents a landmark in medical history and will intensify research in this field.

It was recognized that if the effects produced on the irradiated persons could be related to the exact doses of radiation they had received, valuable knowledge about the biological consequences of acute and high-level radiation exposure on a quantitative basis would be obtained. Although the Institute estimated that the irradiated persons received a total average whole-body dose of 683 rems of neutron- and gamma-radiation, these were not precise enough data, and accordingly the director-general of the International Atomic Energy Agency suggested to the Yugoslav authorities that a dosimetry experiment be conducted by an international team of scientists at Vinca. A formal agreement between the Agency and the Federal Nuclear Energy Commission of Yugoslavia was concluded on February 2, 1960, under which the Agency assumed responsibility for organizing and carrying out the experiment. Yugoslavia agreed to place the reactor and the laboratory at Vinca at the disposal of the Agency and to provide personnel, instruments and services. Experts from Saclay re-designed the control equipment of the reactor and were responsible for the reactor start-up and operation. The 6·5 tons of heavy water needed as moderator were provided free of charge by the U.K. Atomic Energy Authority and arrived at Vinca at the end of March. Twelve French experts, led by J. Weill and J. Furret, arrived with their special equipment from Saclay at the beginning of April, and an American team of seven health physicists from the Oak Ridge National Laboratory, together with their highly specialized equipment, including four 'phantoms' or plastic dummies of men filled with a salt solution, reached Vinca soon afterwards. The reactor first became critical on April 20. On April 22 it was operated at a power of 1 kW. and on April 25 at 5 kW. Simultaneous measurements of the neutron- and gamma-doses were made at points where the persons in the accident in October 1958 were located. The energy distribution of the radiation at these points was investigated, particularly the ratio of the various components.

At the press conference at Vinca, the scientists who had taken part in the experiment, and Dr. Jammet, were present. In response to questions, Dr. G. S. Hurst, of the American team, stated that there was one accident in the United States (that at Oak Ridge in June 1958) in which investigations comparable to those at Vinca were possible. It was not necessary to reconstruct the exact conditions of the incident of October 1958 for the dosimetry experiment, because the techniques of dosimetry did not depend on it—in any event it would have been impossible to do so because of certain unknown factors. It was, however, important to ensure that the configuration of the reactor room was exactly the same as during the accident.

Dr. Jammet explained during the press conference that not all the Yugoslav patients had received the same medical treatment, nor had the results been identical. The Curie Hospital had no fixed programme of treatment of radiation injury. There were always some unknown factors in specific cases and the problem was to make the treatment fit the specific needs of the case. Nevertheless, the experiment at Vinca was "another stone in the edifice of our research in the medical field".

AVIATION HYGIENE AND SANITATION

GENERAL provisions in the International Sanitary Regulations which were adopted by the Fourth World Health Assembly in 1951 require health administrations *inter alia* to ensure so far as is practicable that airports in their territories have at their disposal sufficient organization and equipment for the application of the regulations and are provided with supplies of pure drinking water and effective systems for the removal and safe disposal of excrement, refuse, waste water, condemned food, and other matter dangerous to health. Certain airports (designated as sanitary airports) should also be equipped with an organized medical service and facilities to combat infection. There are no specific provisions, however, on such matters as how pure drinking-water is to be supplied or an effective waste-disposal system organized, health administrations being left to make their own arrangements (*WHO Chronicle*, 14, No. 6; June 1960).

The Assembly outlined several measures that should be taken, in conjunction with the International Civil Aviation Organization, to assist Member States to introduce high standards of hygiene and sanitation. Among them was the preparation of a guide to hygiene and sanitation in the operation of airports open to international traffic. This guide was prepared by a World Health Organization Committee on Hygiene and Sanitation in Aviation. It makes specific recommendations on water, food, and waste. All water for drinking and other personal use by crews and passengers, whether in the air or on the ground, should be free from chemical substances and micro-organisms that might cause illness in any form, and should not only be safe but also attractive, lacking turbidity, colour and disagreeable taste or odour. Preferably, it should come from well-operated public supply systems conforming with acceptable standards. Samples should be taken at least once weekly from representative points, and the results of bacteriological analysis reported to the airport health and operating authorities and used to determine whether the airport water meets the bacteriological standard, and, if not, what corrective measures are required. The water supply should be inspected by a competent sanitary engineer at least once a year and whenever changes are made in the system that might affect the quality of the water.

If water must be drawn from a supply of inferior or unknown quality for use by crews or passengers, it should be given sufficient treatment to destroy cysts of *Entamoeba hystolytica* and the virus of infectious hepatitis; all the other disease organisms generally found in contaminated water will be destroyed by this treatment.

Food should be of good sanitary quality, placed in refrigerators as necessary, and kept scrupulously clean. All meat and fish should be thoroughly cooked before serving. In tropical countries infection with *Ascaris* is widespread, so that raw foods such as green salads and chopped raw vegetables should be avoided. All food should be carefully handled and protected from contamination by insects and other animals, soiled hands, and dirty surfaces. To prevent chemical poisoning, vessels and utensils containing such elements as cadmium and lead should be avoided, the strictest precautions observed regarding the use of poisons around food areas, and only food of the highest quality purchased. Because of the special hazards of foods like cream, milk and milk products, cracked eggs (especially duck's), 'shellfish', gravies and meat salads and dressings, preference should be given to plain, simple foods requiring the minimum of handling. Raw oysters and other shellfish should not be used unless it is certain that they are fresh, uncontaminated, and come from clean areas. Milk and milk products should be sterilized and kept in bottles; and the opened bottles should remain in refrigerators.

Special cleansing and germicidal treatment should be given to dishes and utensils before use.

The guide contains a detailed description of the handling and disposal of toilet wastes, sewage, air-sickness containers, and refuse, at airports and on the aircraft. Particular care should be taken to avoid spillage or open exposure, since this leads to fly and rat infestations. If practicable, the final disposal of garbage should be at a point remote from the airport; if not, it can be burned, buried, or ground and discharged into a sewer; open pits or dumps are unsatisfactory because of flies and rats. On aircraft, the provision of watertight receptables, easily cleanable floorings, soil-cans, tanks and wash-basins is important.

Rooms used by crews and passengers in transit at international airports should be effectively mosquito-proofed in areas where mosquitoes and flies are prevalent. Every day, any mosquitoes that may have gained entrance should be destroyed. Walls and ceilings, particularly in sleeping quarters, should be sprayed regularly with residual insecticide, in accordance with the recommendations of the WHO Expert Committee on Insecticides.

To carry out this work, airports must have adequate staff, equipment and premises. The adequacy and efficiency of ground installations are of interest and concern to many groups; to increase efficiency and co-operation, committees, such as national and local facilitation committees, should review procedures and practices and study possible improvements.

CENTENARY CELEBRATIONS OF W. M. BAYLISS AND J. S. HALDANE IN MOSCOW

A JOINT meeting of the U.S.S.R.–Great Britain Society and the Moscow Physiological Society was recently held at the Friendship House in Moscow. The meeting was devoted to the centenary of the births of W. M. Bayliss and J. S. Haldane.

The meeting was opened by Prof. V. Parin, president of the Physiological Society. Prof. K. Koshtoyants, a prominent Soviet physiologist and head of the Department of Physiology of the Moscow State University, discussed the life and research work of Prof. Bayliss. "Bayliss's name is one of the brightest in the history of world physiology", he said. Among other things, Prof. Koshtoyants said that soon after the Civil War a State Publishing House was set up in the Soviet Union. It planned the publication of a number of major works of world science, and one of the first in the list of these works was Bayliss's famous book "Principles of General Physiology". In 1927, Russian translations of two monographs by Bayliss were published. Prof. Koshtoyants went on to speak of the profound mutual interest in, and respect for, each other of Bayliss and the equally great Russian physiologist Ivan Pavlov. It so happened that Pavlov in Russia and Bayliss and Starling in Britain did parallel research on the regulation of the activity of the pancreas, but came to opposite conclusions. According to Pavlov, the gland produced its secretion as a result of nervous signals, whereas according to Bayliss the gland was made to function by an active chemical agent contained in the blood. A thorough joint investigation of the experiments showed that the Russian and the British physiologists were both right, and as a result a comprehensive modern conception of the regulation of pancreatic secretion was formed.

Prof. L. Shik then spoke of the research work done by J. S. Haldane. As a result of Haldane's researches, he said, basic conceptions were formed of the physiology of respiration. Haldane's experiments were distinguished for their remarkable outward simplicity, which was actually the result of a good deal of thought and precise preliminary calculations. Unlike many representatives of the so-called 'pure science', Haldane was interested in the problems of applied physiology, and his research on the physiology of divers and airmen provided scientific grounds for modern practical measures ensuring man's safety in the conditions of changing barometric pressure. Many of his experiments, some of which were quite dangerous, he conducted on himself. No wonder that when the well-known Russian physiologist, A. Samoilov, urged young research workers to investigate directly the human organism, he always referred to Haldane's successful experiments.

Some of the members of the U.S.S.R.–Britain Society prepared for the jubilee meeting an exhibit with the portraits of Bayliss and Haldane and a display of Russian translations of their books.

D. A. SAKHAROV

IS HYPERCONJUGATION NECESSARY?

MULLIKEN, Reike and Brown[1] proposed a new type of conjugation, 'hyperconjugation', based on the fact that the heat of hydrogenation of an olefin is appreciably decreased by the presence of alkyl substituents on the unsaturated carbon atom. A necessary effect of hyperconjugation would be to change the lengths of the C—H bond in the alkyl group and the C—C bond adjacent to a double or triple bond. The C—Me distance in toluene[2] is 1·51 Å. and in methyl acetylene and acetonitrile[3] it is 1·46 Å., compared with the normal C—C distance of 1·54 Å. in ethane. It was pointed out that part of these bond shortenings was due to the change in the atomic radius from tetrahedral to trigonal or digonal carbon and about one-half of the observed shortening was due to hyperconjugation[4].

Hyperconjugation was considered to be responsible for the dipole moment of alkyl benzenes. The ionization potentials of methylated ethylenes[4,5] and the absorption spectra[5,6] were also given as evidence for hyperconjugation. The view that C—H hyperconjugation is the predominant mode of electron release by alkyl substituents when attached to an electron-demanding system was originally proposed by Baker and Nathan as an explanation of certain rate and equilibrium data. The Baker–Nathan effect was in the order Me > Et > *i*-Pr > *t*-Bu, which is exactly the reverse of what one would expect if the electron release were by the inductive mechanism.

Although a great deal of physical and chemical evidence has been accumulated in support of the idea of hyperconjugation, recently there have been a number of observations which cannot be explained in a simple fashion by hyperconjugation, and the situation has become controversial.

Recent molecular structure investigations[6,7] in several laboratories, on derivatives of acetonitrile and methyl acetylene, have conclusively shown that the length of a carbon–carbon single bond adjacent to a triple bond (that is, a bond between sp and sp^3 carbon atoms) is always close to 1·46 Å., independent of the substituents on the sp^3 carbon. So it is concluded that the shortenings in the C—C bonds between sp and sp^3 carbon atoms (0·08 Å.) or sp^2 and sp^3 carbon atoms (0·04 Å.) may not result from any kind of conjugation, and that it is likely that these bond contractions are entirely due to the changes in the covalent radius of carbon with hybridization. The bond-lengths in relation to hyperconjugation have been discussed in fair detail by Sutton[8]. The evidence for hyperconjugation from calorimetric data is no longer valid, since the change in the C—C bond energies with bond-lengths (that is, with hybridization) was not taken into account in these calculations. So the effects attributed to hyperconjugation of the alkyl groups may equally be due to the introduction of a stronger C—C bond. In general, the stabilization of an unsaturated system by alkyl substitution has been found to be essentially independent of the nature of the alkyl group and cannot be accounted for in terms of steric effects[9].

The evidence for hyperconjugation from dipole moment data also needs to be re-interpreted. Since the electronegativity of an sp or sp^2 carbon is different from that of an sp^3 carbon, the resulting bonds (between any two differently hybridized carbon atoms) should have different polarities. In fact, Petro[10] has reported excellent agreement between the observed and calculated dipole moments of C—C bonds between two differently hybridized carbon atoms. He concludes that hyperconjugation structures do not explain the non-zero dipole moment of toluene. Recently, Brown[11] has studied the dipole moments of alkyl benzenes and the results are not conclusive.

The earlier evidence for hyperconjugation on the basis of ionization potentials and absorption spectra was not unambiguous because these deal with both the electronic ground-states and the excited states of molecules. The ionization potentials of the alkyl groups are actually found to be in the inductive order[12]. However, a simple molecular orbital treatment by Streitwieser and Nair[13] seems to indicate that the methyl group can be treated as a 'heteroatom' donating two electrons to the π-system. The evidence from absorption spectra has met with a number of objections[14–16]. An explanation based on steric hindrance to solvation of the electron-deficient sites in the vicinity of the alkyl substituent has been suggested.

In general, it may be said that the effect of alkyl groups on the near ultra-violet absorption spectra of aromatic compounds is not consistent. A recent study of the $n \rightarrow \pi^*$ transitions of aliphatic ketones and nitro compounds in different types of solvents by Rao *et al.*[17] seems to show the predominant role of resonance interaction of the alkyl groups in the excited states of these molecules. An earlier investigation by Rao, Goldman and Lurie[18] of the infra-red carbonyl frequencies in aliphatic ketones had indicated that mainly inductive effects were important in the ground-states of these molecules.

The chemical evidence for hyperconjugation has been a subject of controversy. The Baker–Nathan order Me > Et > *i*-Pr > *t*-Bu, has been found in a number of reactions and has been explained in terms of the C—H hyperconjugation[19]. The importance of C—C hyperconjugation in the *t*-butyl group has also been pointed out[20]. The relative importance of C—H and C—C hyperconjugation in aliphatic and aromatic series has been evaluated by the application of the linear inductive energy relationship[21,22]. McCaulay and Lien[23] have shown that C—H hyperconjugation must be an important mode of electron release in the methyl-substituted aromatic cations. De la Mare[24] has discussed the possibility of OH and NH hyperconjugation. Shiner[25], Lewis[26] and Taft and co-workers[27] have shown that hyperconjugation is one of the important sources of secondary isotope effects. Shiner[25] considers three possible effects on hyperconjugation: steric, substituent and solvent effects. Brown[28] has recently discussed the relative importance of the dispersion and induction forces in alkyl benzenes. Berliner[19] is of the opinion that although the effect of the alkyl groups in individual reactions can be interpreted in different ways (based on solvent or steric or inductive effects), hyperconjugation appears to be the most satisfactory general explanation for the behaviour of remote alkyl groups on the benzene ring where the Baker–Nathan order is observed.

The information from chemical reactivity regarding the possible role of hyperconjugation is not consistent, and does not distinguish such a contribution in the ground-state from that in the transition state of the molecule. Further, there is no clear evidence for any marked degree of hyperconjugation from physical measurements on the ground-states of molecules. These arguments have been forcefully expressed by Dewar and Schmeising[29], who have developed a new method for calculating bond-lengths and resonance energies for conjugated systems taking the σ-bond compression into consideration. They argue that if the π-electron resonance is unimportant in ordinary conjugation (as in the case of butadiene), it should be much more so in hyperconjugation. But Mulliken[30] has found it desirable explicitly to classify conjugation and hyperconjugation into two types: isovalent and sacrificial (ordinary). He also suggests further classification of isovalent conjugation and isovalent hyperconjugation into sub-types. Isovalent hyperconjugation has been suggested as being more important than ordinary hyperconjugation. The Baker–Nathan effect has been described as differential hyperconjugation. Apparently there are no theoretical reasons for expecting differences between C—C and C—H hyperconjugation[30].

In my view, the present status of hyperconjugation may be summarized as follows: while the contribution from hyperconjugation seems unimportant in the electronic ground-states of molecules, it may be prominent in the excited or the transition states of molecules.

I have benefited greatly from stimulating discussions with colleagues in Purdue University and the University of California. Many of the papers referred to as appearing in *Tetrahedron* were published in a special issue of that journal containing the proceedings of a Conference on Hyperconjugation held at Indiana University in June 1958.

THE 'GBR EXPERIMENT': A TRANS-ATLANTIC FREQUENCY COMPARISON BETWEEN CÆSIUM-CONTROLLED OSCILLATORS

By J. A. PIERCE
Cruft Laboratory, Harvard University, Cambridge, Mass.

G. M. R. WINKLER
U.S. Army Signal Research and Development Laboratory, Ft. Monmouth, New Jersey

AND

R. L. CORKE
Post Office Research Branch, Dollis Hill, London, N.W.2

For several years the temporal variation of phase, and hence the frequency, of a 16-kc./s. signal from Rugby, England, has been observed at Cambridge, Massachusetts[1,2]. During this period the transmission has been controlled by an Essen ring crystal oscillator and the reference at Cambridge has been one of several crystals or, since early 1958, an Atomichron.

The problem of resolving the observed fluctuations of phase into components caused on the propagation path and those produced by one or both oscillators has been attacked by choosing short periods (usually 4 or 5 days) when operation seemed especially stable. For these short lengths of time, internal evidence seemed to indicate that the oscillators were behaving in a consistent way and the observed deviations were taken as representing primarily variations in transmission time. The results of this somewhat dubious procedure indicated standard deviations of phase of about 1 or 2 μsec. When observations were extended over 24 hr., the corresponding precision of frequency measurement should have been about two parts in 10^{11}.

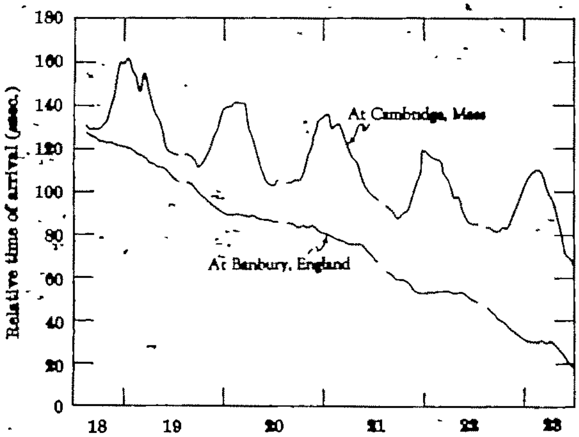

Fig. 1

Unfortunately, all long-term frequency comparisons have yielded standard deviations of 2 or 3 parts in 10^{10}. The source of this discrepancy of ten times in precision has been assumed to be frequency uncertainty in crystal oscillators. Proof, however, was lacking, and the corollary assumption that the long-distance transmission is more stable than very good oscillators has not been easily accepted in some quarters.

In this dilemma, a simple experiment was performed during September and October 1959. A photographic record of the phase of the Rugby signal was made at Banbury, Oxfordshire, England, where transmission vagaries on the 24-mile path from Rugby could be assumed to be unimportant. This record was, in every way, exactly similar to one simultaneously made in Cambridge, Massachusetts. The Banbury record was referred to Atomichron No. 111 and the Cambridge record was made in terms of Atomichron No. 112. Thus, by subtraction, the effects of the fluctuations of the crystal controlling the transmitter could be removed.

An example of the observed phase (or time of arrival) variations is given in Fig. 1. The Cambridge data show the normal day-to-night propagational variation of some 34 μsec. Both curves indicate some crystal oscillator variation, and the gradual divergence between the curves indicates that there was some frequency difference between the two Atomichrons.

It was hoped that this experiment would yield at least a month of continuous operation at both receivers. This hope was not realized, because of a number of minor interruptions which caused loss of continuity of phase at one point or the other. There were, however, two periods of ten days or so when operation was entirely satisfactory. During the first of these, the difference in phase between Cambridge and Banbury is shown in Fig. 2. Here it can scarcely be denied that the frequency of one of the Atomichrons was shifting with respect to the other, as shown by the gradual change in slope of the curve, when diurnal variation is removed. In spite of this effect, excellent day-to-day consistency is observed.

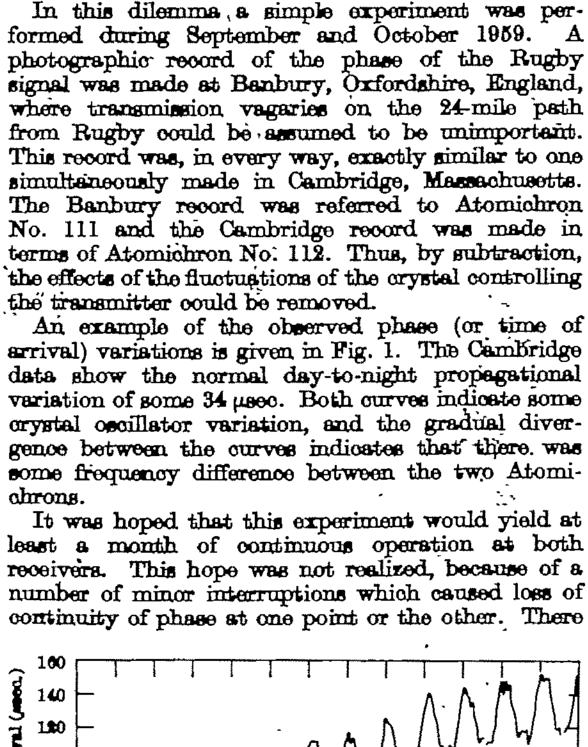

Fig. 2

The other period of satisfactory operation gave the difference record of Fig. 3. In this case the sense of the frequency difference between the Atomichrons had reversed, but the difference seems small and quite stable.

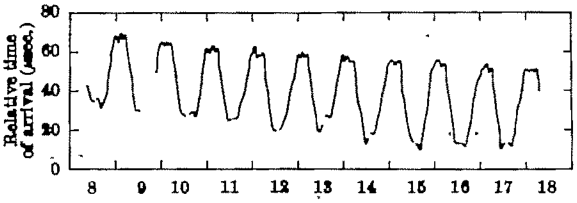

Fig. 3

In a record of this sort, any chord has a slope that is a measure of the frequency difference for the interval between its end points. The scale of the figures exhibited is such that even the steep slopes at sunrise and sunset represent frequency variations of only about two parts in 10^9. To remove the diurnal variation it is simple to take measurements over 24 hr. or multiples thereof. This might be done, for example, from noon to noon. In this article, however, each day's record (from 15h. U.T. to 13h. U.T. on the following day) is reduced to a single value by averaging together the 23-hourly values.

The time-of-arrival values thus obtained are shown in the second column of Table 1. Values are missing for October 8–10 (although some are shown in Fig. 3)

‡ Including a few values for intervening and subsequent dates.

because of a recording failure on October 9 which lost some of the 23 hourly values on that day. Column 3 of Table 1 gives the frequency difference derived from the successive phase values of column 2. Because of the curvature shown in Fig. 2, which may have been caused by the incipient failure of the klystron in Atomichron 112 that occurred on September 27, a progressive change in frequency has been assumed. The deviations of column 4 of Table 1, therefore, imply a linear change in frequency or a parabolic change in time of arrival. It will be seen that the frequencies are consistent to a few parts in 10^{11}.

At the time of these observations a second Atomichron, No. 117, was also operating at Banbury. It was not involved in the measurements hitherto discussed, but beats were counted between the two local outputs. These were not continuously reported, and the sense of the frequency difference was not determined. The values shown in column 5 of Table 1 have been assumed positive, for computation of the deviations in column 6.

It is perhaps significant that the r.m.s. differences at the bottom of Table 1 are so similar in magnitude. This value seems to represent the precision with which two Atomichrons can be expected to produce the same frequency.

The standard deviations show the accuracy with which the Rugby signal can be measured, in Cambridge and in Banbury, in an interval of 24 hr. This precision is, at least on the average, inversely proportional to the duration of measurement. Although there is no firm reason to assume that the frequency fluctuations of three Atomichrons are identical, the similarity between the two standard deviations is striking. It appears, as suggested initially, that the actual fluctuations in transmission time are of the order of two microseconds and the corresponding contribution to the errors of trans-Atlantic frequency measurement is about two parts in 10^{11}, for a duration of measurement of 24 hr.

Acknowledgment is made to the Engineer-in-Chief of the British Post Office for the facilities made available at the Post Office Radio Measuring Station, Banbury, Oxfordshire, England. We thank Mr. W. N. Genna and the staff at Banbury for their assistance.

CHEMICAL AND PHYSICAL PROPERTIES OF THE SMALL DEOXYRIBONUCLEIC ACID COMPONENT OF CRYSTALLINE CYTOCHROME B_2

By Dr. M. D. MONTAGUE and Prof. R. K. MORTON

Department of Agricultural Chemistry, Waite Agricultural Research Institute, University of Adelaide

THE recent report by Kit[1] concerning the fractionation of deoxyribonucleic acid on columns of 'Ecteola-cellulose' prompts us to report our experience with the deoxyribonucleic acid component associated with crystalline cytochrome b_2 from baker's yeast.

Cytochrome b_2 crystallized by the procedure of Appleby and Morton[2] is a flavohaemoprotein[2,3] containing a deoxyribonucleic acid component[4] and having L(+)-lactate dehydrogenase activity. The deoxyribonucleic acid component was dissociated from the enzyme, which had been crystallized three times, by anaerobic dialysis at pH 8·0 against 0·7 saturated ammonium sulphate solution[4] containing 0·15 *M* sodium lactate and 10^{-4} *M* ethylenediamine tetraacetate. The solution of nucleic acid was dialysed against several changes of 0·01 *M* potassium phosphate buffer, pH 7·0 and about 500 μgm. of the nucleic acid were loaded on to a column (3·5 × 1 cm.) of 'Ecteola-cellulose' (type 20, Brown Co., Berlin, New Hampshire). A gradient of sodium chloride in 0·01 *M* potassium phosphate buffer, pH 7·0, was used to elute the components. Approximately 85 per cent of the material absorbing at 260 mμ was eluted as a single peak between 0·5 and 0·7 *M* sodium chloride. Re-chromatography on the same column using a less-steep gradient of sodium chloride gave a single peak between the same limits of salt concentration. Alternate dialysis and freeze-drying was used to concentrate the material and to avoid possible denaturation due to high concentrations of salt. Table 1 shows the optical properties of the deoxyribonucleic acid from cytochrome b_2.

Table 1. OPTICAL PROPERTIES OF THE DEOXYRIBONUCLEIC ACID COMPONENT OF CRYSTALLINE CYTOCHROME b_2

	λ_{max} (mμ)	ε(P) (max.)	λ_{min} (mμ)	ε(P) (min.)	$\frac{E_{250\ m\mu}}{E_{260\ m\mu}}$	$\frac{E_{280\ m\mu}}{E_{260\ m\mu}}$	$\frac{E_{290\ m\mu}}{E_{260\ m\mu}}$
In sodium acetate (0·01 *M*) pH 7·0	260	6,600	233	2,620	0·82	0·51	0·19
In NaOH (0·05 *N*)	260	7,800	235	4,300	0·80	0·46	0·12
In HCl (0·01 *N*)	260	8,650	232	2,740	0·76	0·56	0·27

After removing most of the ribonucleic acid by fractionation with sodium chloride, Kirby's[5] procedure was used to isolate the bulk deoxyribonucleic acid of yeast extracted from the same type of baker's yeast as used for preparation of the cytochrome b_2. The bulk deoxyribonucleic acid was chromatographed on the same column as was used for the deoxyribonucleic acid from cytochrome b_2. A component (fraction 6–7), comprising 15 per cent of the total material absorbing at 260 mμ, was eluted with 0·6–0·7 *M* sodium chloride. It will be noted that the deoxyribonucleic acid component from cytochrome b_2 was eluted between 0·5 and 0·7 *M* sodium chloride under similar conditions.

Table 2 shows the base compositions of the deoxyribonucleic acid from cytochrome b_2, of the bulk

Table 2. BASE COMPOSITIONS OF DEOXYRIBONUCLEIC ACID PREPARATIONS FROM BAKER'S YEAST*

Preparation	Guanine	Cytosine	Adenine	Thymine	(Adenine + Thymine) / (Guanine + Cytosine)

* The procedures are described elsewhere (refs. 4, 6). The results are expressed as a percentage of total bases; the recovery was 92–96 per cent in each case.

† Fraction eluted between 0·6 and 0·7 *M* sodium chloride from 'Ecteola-cellulose' column.

‡ Appleby and Morton (ref. 4) found a base ratio of 2·6 from analyses on whole enzyme.

deoxyribonucleic acid from yeast, and of fraction 6–7 from this preparation.

There was a 30 per cent increase in extinction at 260 mμ after digestion of 250 μgm./ml. of the deoxyribonucleic acid from cytochrome b_2 in 0·02 *M* magnesium chloride with 2 μgm./ml. of crystalline pancreatic deoxyribonuclease at *p*H 7·0; there was no initial lag in the reaction, in contrast to the reaction of the same enzyme with the bulk deoxyribonucleic acid of the yeast. The component from cytochrome b_2 was not degraded by snake venom phosphodiesterase.

Work on the end-group of the deoxyribonucleic acid from cytochrome b_2 has been carried out, the deoxyribonucleoside components at the ends of the chains terminated by 5′-phosphate groups being released by enzymic degradation. All incubations were carried out at room temperature (about 20° C.). A solution containing 270 μgm. of the nucleic acid from cytochrome b_2 in 0·02 *M* magnesium chloride at *p*H 7 was incubated for 16 hr. with potato phosphomonoesterase (free of phosphodiesterase activity) and then heated at 100° C. for 2 min. to destroy the phosphatase activity. It was then digested with crystalline pancreatic deoxyribonuclease for 10 hr. The solution was adjusted to *p*H 8·9 and then incubated for 12 hr. with snake-venom phosphodiesterase (free of phosphomonoesterase activity). The solution was then heated at 100° C. for 1 min., and the clear supernatant obtained after centrifuging was chromatographed on Whatman paper using water-saturated *n*-butanol (100 ml.)–ammonia (1 ml. of solution, specific gravity 0·880). Two components, with R_F values of 0·22 and 0·30, were identified by their ultra-violet absorption spectra as derivatives of guanine and cytosine respectively. Neither adenine nor thymine derivatives were detected. The amounts of nucleosides isolated were too small to determine the quantities of each present with high accuracy, but from the estimates of the amounts released, the molecular weight of the nucleic acid is 10,000–12,000.

The sedimentation coefficient of the deoxyribonucleic acid from cytochrome b_2 was measured using a 'Spinco' model *E* ultracentrifuge fitted with ultraviolet optics. At a concentration of approximately 0·003 per cent of nucleic acid in 0·01 *M* potassium phosphate, 0·078 *M* sodium chloride at *p*H 7·0 ($\Gamma/2$, 0·10) values for $S_{20,w}$ of 5·6–5·9 svedbergs were obtained. A preliminary diffusion experiment using the ultracentrifuge with a synthetic boundary cell indicated that the molecular weight of the nucleic acid is 10,000–20,000. No marked heterogeneity of the sedimenting nucleic acid was observed. We are grateful to Mr. J. McD. Armstrong for these measurements.

Since nucleotide and hæm analyses of crystalline cytochrome b_2 indicate that the minimum molecular weight of the deoxyribonucleic acid component of the enzyme is about 5,000[4], the end-group assays and work on sedimentation establish that the actual molecular weight in solution is approximately 10,000.

The work by Kit[1] on the fractionation of various deoxyribonucleic acid preparations on 'Ecteola-cellulose' (type 20, Brown Co.) has shown that the elution pattern depends markedly on the method of isolation of the nucleic acid. Much of the deoxyribonucleic acid of low molecular weight eluted by neutral salt solution appears to result from the degradation of larger molecules by a number of mechanisms including heat denaturation, action of deoxyribonuclease and mechanical cleavage when the cells are ruptured. Nevertheless, if precautions are taken to eliminate or reduce these degradative processes, the deoxyribonucleic acid still contains material of low molecular weight, and so far no bulk deoxyribonucleic acid has been isolated which does not contain at least 5 per cent of small components. Thus the possibility that the cell normally contains a complement of deoxyribonucleic acid of low molecular weight has still to be considered.

The function of the deoxyribonucleic acid of crystalline cytochrome b_2 is not known. It is not necessary for enzymic activity[4]. Under conditions of low ionic strength, the enzyme does not crystallize in the absence of this component[4] and it may be that the nucleic acid provides the necessary rigidity for crystallization of this protein. It is significant that the ratio of (adenine + thymine) to (guanine + cytosine) for the nucleic acid of cytochrome b_2 is consistently 2·4–2·6, as compared with the value of 1·95 for the bulk deoxyribonucleic acid of the same yeast (Table 2).

The constancy of composition indicates that the deoxyribonucleic acid of crystalline cytochrome b_2 is a specific component of the yeast cell rather than a small molecule formed by random degradation of larger nucleic acid molecules; in the latter case, the base composition of the nucleic acid would be expected to vary among different preparations. The base ratio found in the component (fraction 6–7) from the bulk deoxyribonucleic acid of yeast (Table 2) emphasizes this conclusion.

The constancy in behaviour of different preparations during chromatography on 'Ecteola-cellulose', the sedimentation and diffusion characteristics, and the end-group assay all indicate that the deoxyribonucleic acid component from crystalline cytochrome b_2 is probably a homogeneous material of low molecular weight (10,000). It therefore appears to represent a suitable material with which to investigate the sequence of nucleotides in naturally occurring deoxyribonucleic acid. A detailed account of these investigations and of further work with this material will be reported elsewhere.

MECHANISM OF STARCH BIOSYNTHESIS

By DR. MARIA A. RONGINE DE FEKETE*, DR. LUIS F. LELOIR and DR. CARLOS E. CARDINI

Instituto de Investigaciones Bioquímicas "Fundación Campomar", and Facultad de Ciencias Exactas y Naturales, Obligado 2490, Buenos Aires

SINCE the classical work of Hanes[1] some workers consider that starch synthesis *in vivo* is catalysed by phosphorylase. Nevertheless, others have raised doubts on this hypothesis. Thus Ewart *et al.*[2], from measurements of the ratio of inorganic phosphate to glucose-1-phosphate, concluded that: "phosphorylase is not involved in the synthesis of starch . . . but the role of phosphorylase in the normal metabolic breakdown . . . is not questioned" (cf. also Rowan and Turner[3]). Furthermore, Stocking[4] reported that starch synthesis in leaves is initiated in the chloroplasts, where phosphorylase could not be detected.

The problem of starch synthesis is similar to that of glycogen synthesis in animal tissues. The synthetic role of phosphorylase *in vivo* has been challenged on the basis of the following facts: (*a*) the unfavourable ratio of inorganic phosphate to glucose-1-phosphate in tissues; (*b*) agents which increase the concentration of phosphorylase, such as epinephrine and glucagon, produce glycogen breakdown[5]; and (*c*) in certain diseases phosphorylase is absent in the muscles, although normal or increased amounts of glycogen are present[6].

If these facts are sufficient to rule out phosphorylase as the enzyme responsible for glycogen synthesis, the only enzyme which can take its place, so far as we know, is glycogen synthetase[7], which catalyses the transfer of glucose from uridine diphosphate glucose to glycogen forming a new α-1 : 4 linkage. On the other hand, it is known that uridine diphosphate glucose acts as glucose donor in plants. Thus enzymes catalysing the synthesis of sucrose[8], sucrose phosphate[9], and callose[10] have been described. The latter is a β-1 : 3 glucan[11] discovered many years ago and believed to have a role in the physiology of sieve tubes and in wound reaction in plants[12].

All this suggests that uridine diphosphate glucose should be involved in starch synthesis. Although incubation of radioactive uridine diphosphate glucose with different plant materials usually resulted in the incorporation of radioactivity in the polysaccharide fraction, the product formed was insoluble in hot water, was not hydrolysed by β-amylase and was presumably callose.

Since glycogen synthetase has been found to be strongly adsorbed on glycogen (ref. 7*c*), we have looked for a starch-synthesizing enzyme in starch granules. In preliminary experiments, radioactive uridine diphosphate glucose was incubated with freshly prepared potato starch and it was found that there was some incorporation of radioactivity in the fraction which became soluble by the subsequent action of α-amylase. More active preparations were obtained from beans as follows. Freshly harvested immature dwarf string beans (*Phaseolus vulgaris* var. Bountiful) were used. The cotyledons and the embryos were ground in a mortar with two volumes of water. The suspension was filtered through cheesecloth and centrifuged 5 min. at 3,000 rev./min. The precipitate was resuspended in several volumes of water and recentrifuged three times. The white precipitate was then suspended in four volumes of acetone at − 15° C., centrifuged at 0° C.; this procedure was repeated three times, after which the precipitate was dried *in vacuo*. This preparation could be stored for months at − 15° C. with no decrease in activity.

The bean starch fraction (2 mgm. containing 6 μgm. of protein) was incubated at 37° C. for 3 hr. with 0·21 μmole of uridine diphosphate glucose containing 7,850 counts/min. of carbon-14 in the glucose moiety, 2 μmoles of glycine buffer of pH 8·4, 0·05 μmole of ethylenediamine tetraacetate in a final volume of 15 μl. After incubation, 0·5 ml. of 80 per cent ethanol was added. The soluble fraction was spotted on paper and chromatographed with ethanol–ammonium acetate of pH 7·5 (ref. 15). The uridine diphosphate and uridine diphosphate glucose spots were eluted from the paper and the absorbancy at 260 mμ, radioactivity and uridine diphosphate were measured. The insoluble fraction was washed with ethanol and counted. Blanks without and with uridine diphosphate glucose added after incubation were run at the same time. Furthermore, it was found that the bean starch fraction did not destroy added uridine diphosphate.

The changes occurring on incubation of the bean starch fraction with radioactive uridine diphosphate glucose are shown in Table 1; these results indicate a correspondence between disappearance of uridine diphosphate glucose, formation of uridine diphospate and incorporation of glucose into the starch fraction.

Table 1. ANALYSIS OF SUBSTRATES AND PRODUCTS

	μmole	μmole
Disappearance of uridine diphosphate glucose	0·02*	0·016†
Formation of uridine diphosphate	0·017*	0·015‡
Glucose-U-^{14}C incorporated into starch		0·017‡

* Calculated from absorbancy at 260 mμ.
† Calculated from radioactivity.
‡ Estimated with pyruvate kinase (ref. 7*c*).

The identity of the product formed was investigated as follows. The starch fraction after incubation with radioactive uridine diphosphate glucose was thoroughly washed with aqueous ethanol, suspended in water, heated for 10 min. at 100° C. and then treated with β-amylase. Wheat β-amylase was allowed to act for 12 hr. at 37° C., and 3 volumes of methanol were added. The soluble fraction was evaporated, spotted on paper and chromatographed with butanol/pyridine/water (6 : 4 : 3 v/v)[13] as solvent. As shown in Fig. 1*a* the radioactivity was found to migrate like maltose. For further confirmation of the identity of the substance, the 'maltose' eluted from the paper after chromatography was submitted to electrophoresis with borate buffer[14]. As shown in Fig. 1*b*, the radioactivity migrated with the 'maltose'. Under these conditions, cellobiose, laminaribiose and gentiobiose are neatly separated from maltose.

Similar results were obtained with α-amylase. Saliva (0·1 volume) was allowed to act for 30 min. at 37° C. and the samples processed as described for β-amylase. The results were similar except that radioactivity appeared also in the maltotriose spot.

---

*Post-Doctoral Fellow of the University of Buenos Aires.

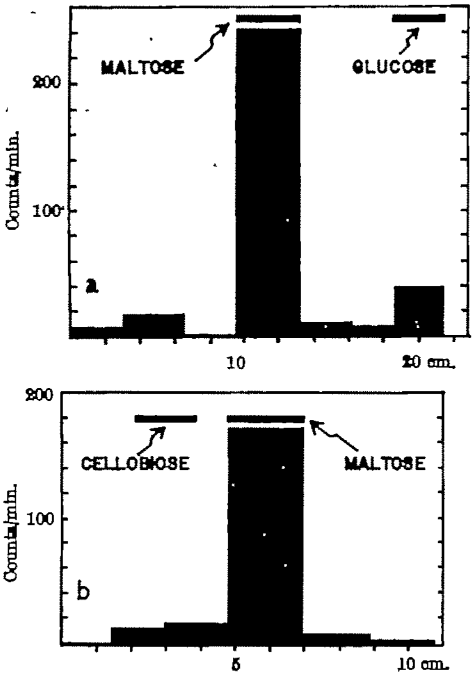

Fig. 1 (*a*) Paper chromatography; and (*b*) paper electrophoresis of reaction product after treatment with β-amylase

These results are consistent with the following formulation:

$$\text{uridine diphosphate glucose} + \text{acceptor} \rightarrow \text{uridine diphosphate} + \alpha\text{-glucosyl-1,4-acceptor} \quad (1)$$

in which the acceptor is starch.

Other experiments were carried out in order to study the specificity of uridine diphosphate glucose as glucose donor. As shown in Table 2, glucose phosphates and sucrose showed some incorporation of radioactivity but much less than uridine diphosphate glucose.

Table 2. Donor Specificity

Bean starch fraction (8 mgm.) incubated 1 hr. under conditions similar to those indicated in Table 1 with about 0·2 mole of substrates indicated

Donor	Counts/min. added	Counts/min. recovered in 'starch' fraction
Uridine diphosphate glucose	5,300	590
Glucose-1-phosphate	8,000	190
Glucose-6-phosphate	10,000	210
Sucrose	8,500	180
Glucose	10,000	0

Sucrose has been tested as glucose donor in other experiments with various plant tissue preparations with negative results. The well-known ready conversion of sucrose into starch *in vivo* might take place indirectly with uridine diphosphate glucose as an intermediate. The formation of uridine diphosphate glucose from sucrose has been detected (refs. 8, 9) and may be written as follows:

$$\text{sucrose} + \text{uridine diphosphate} \rightleftharpoons \text{uridine diphosphate glucose} + \text{fructose} \quad (2)$$

The addition of reactions (1) and (2) would result in the formation of starch from sucrose.

This investigation was supported in part by a research grant (No. *G*-3442) from the National Institutes of Health, U.S. Public Health Service and by the Consejo Nacional de Investigaciones Cientificas y Técnicas.

ANALYSIS OF METABOLIC RATES AT THE CELLULAR LEVEL

By L. G. LAJTHA, R. OLIVER, R. J. BERRY and ELIZABETH HELL

Radiobiology Laboratory, Department of Radiotherapy, Churchill Hospital, Oxford

DURING the course of autoradiographic work with iron-59 and tritium, carbon-14, or sulphur-35 labelled compounds in human bone marrow cells, Ehrlich mouse ascites cells, or in mouse thymus, spleen, and intestine, it was noticed that the grain counts over labelled cells showed a considerable spread. This spread was significantly greater than that for a Poisson distribution about a single mean corresponding to the statistical variation of radioactive disintegrations. In short-term incubations the grain counts over the labelled cells measure uptake during unit time per cell (that is, uptake rate per cell), and some biological variation is natural even in a homogeneous population of cells, so this finding was not unexpected. However, variations in the observed spread warranted a closer analysis of the distributions of grain counts, and these have indicated certain qualitative differences in the uptake pattern of various labelled compounds and in different cell types.

Theoretical Considerations

(1) If the uptake rate is constant throughout the cell population the same amount of radioactive material will be incorporated into each cell, and the variation in the grain count over cells will be entirely due to the statistical fluctuation in the number of disintegrations occurring during the time of exposure. This would lead to a Poisson distribution about a mean value with a standard deviation equal to the square root of the mean. As the number of grains over each cell is necessarily small, this deviation will be appreciable. Thus for a typical mean of 45 grains the standard deviation would be $\sqrt{45}$ or 6·7, that is, about 15 per cent. This distribution is shown in Fig. 1*A*.

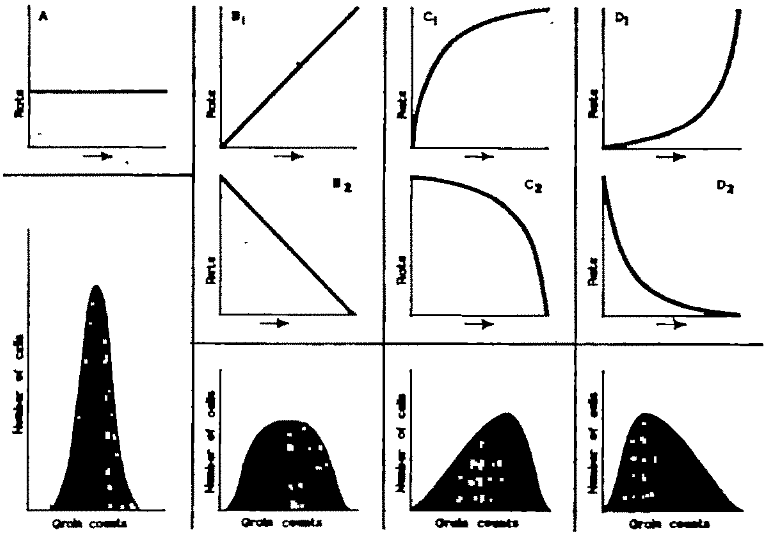

Fig. 1

In a non-growing population of cells a constant rate of uptake may indicate a steady rate of turnover or synthesis of a compound. However, some biological variation would be expected, especially between the young and the senescent members of the population, so that the observed spread would exceed that of the ideal Poisson distribution (Fig. 1*A*) and depend partly on the relative proportions of 'normal' and 'senescent' cells.

In a non-synchronous growing population of cells, theoretically a number of possible variations in the rate of uptake may be considered. A constant rate of uptake would lead to the type of distribution of grain count discussed above.

A linear increase or decrease of the rate of uptake would result in an even distribution of low and high rates and the grain count distribution would ideally follow the symmetrical type of curve shown in Fig. 1*B*. If, however, the rate of uptake increases or decreases exponentially, then the resulting grain count distribution would be asymmetrical as illustrated in Figs. 1*C* and *D*.

(2) In a growing cell population the cells increase their mass during interphase from a '2*n*' to a '4*n*' value to yield two '2*n*' cells after mitosis. Therefore a constant uptake-rate in such a population would imply a synthesis of a compound (or structure) which would not be functional until after mitosis, or a turnover of a compound (or structure) which does not reduplicate until mitosis.

A linear increase in uptake rate would correspond to a constant rate of production of new, for example enzyme, molecules (responsible for the uptake of the compound investigated); however, it would also mean that the 'producer' of the new enzyme molecules is not reduplicated (or if so then is not functional) until mitosis. A linear decrease would imply a similar constant rate of production of an inhibitor of uptake.

Such processes leading to linear changes in uptake rate would seem to be unlikely where the function is continuous throughout the interphase—a condition which would be indicated by effectively all cells of the population being labelled in short-term incubations (100 per cent 'positive' cells). However, where significantly fewer than 100 per cent of the cells are labelled, it can be concluded that the function is active only during part of the interphase. In such cases reduplication can occur in the remaining period, and linear rate changes may be conceivable.

Of the possible forms of exponential type of variations in uptake rate the simplest system would correspond to Fig. 1D_1, where the rate of uptake of a material is proportional to the amount of that material already present in the cell. In such a case a doubling of the rate during interphase would be expected, that is, a 1 : 2 change.

The contrasting situation is represented in Fig. 1D_2, where the rate of uptake of a material is reduced proportionally to the amount of the material in question present in the cell. In such a case a halving of the rate during interphase may be expected.

It is possible to differentiate between these two situations as, although the expected grain count distribution curves would be identical as shown in Fig. 1, the distribution curves for the content of the material in the cell would have the same form as the grain-count distribution curve in case of D_1, but of opposite asymmetry in D_2.

A situation where the uptake rate is limited exponentially, possibly by an exponentially decaying inhibitor, is illustrated in Fig. 1C_1, while an exponential build-up of an inhibitor of uptake rate is represented in Fig. 1C_2. Although the grain-count distribution curves are similar, the content distribution curves would again differentiate between the two situations; for C_1 the asymmetry of the two curves would be similar, for C_2 opposite.

Situations C_1 and C_2 for functions occupying the whole of the interphase (100 per cent positive cell population) would imply birth of an inhibitor during mitosis with subsequent decay in C_1; and build-up of an inhibitor with explosive disappearance during mitosis in the case of C_2. While such situations may exist, neither of them is considered as likely for the majority of cell functions as situations D_1 and D_2. Furthermore, in situations C_1 and C_2 there is no *prima facie* reason why the rate change should be limited to 1:2; in fact, rate changes considerably in excess of this could be expected.

In practice, the cell processes may lead to other types of curves (for example, sigmoid or other composite curves), but the above general conclusions on grain-count distribution would still apply. In any event, if the rate changes involved are only of the order of 1:2 it may not be possible—as is shown later—to differentiate between linear and exponential or other types of curves. In cases, however, where the rate changes are significantly greater (for situations C_1 and C_2, and also probably in the case of a sigmoid curve), the differences between the various types of curves may become appreciable.

Two special cases, where uptake is related to cell surface area, may be considered. If uptake rate is proportional to total cell surface, then during one duplication of the cell mass uptake rate would increase from 1:1·6 only. If, however, uptake rate depends on surface area per unit mass (or mass per unit area) then it would decrease from 1:0·8 (or increase from 1:1·26) during one duplication of the cell mass. Consequently, if in a growing population of cells a change of uptake rate less than 1:2 is observed, this may indicate an uptake dependent on surface area, but changes from 1 : 0·8 or 1 : 1·26 are almost certainly indistinguishable from a constant rate.

Master Curves

The curves shown in Fig. 1 are exaggerated for the sake of illustration of the problem. A master curve was therefore drawn for normal distribution with a standard deviation of 30 per cent, corresponding to standard deviations of 15 per cent for a mean grain count of 45 grains per cell, and of 25 per cent for biological variation. This was likely to represent the greatest spread of grain count distribution which could be expected for a population having a nominally uniform uptake rate.

In order to represent the conditions with a linear or exponential increase or decrease in uptake rate the only case considered was for doubling of the rate during the period of uptake. A composite curve was constructed by the summation of five normal distributions with means at 1·1, 1·3, 1·5, 1·7, and 1·9, and standard deviations of 30 per cent, the relative peak ordinates corresponding to the proportion of cells which would, in each case, lie ideally within that range of uptake rate (1·0–1·2, 1·2–1·4, etc.). This procedure, of course, blurs the clear difference between the types of grain count distribution curve shown in Fig. 1, but was more likely to provide distributions similar to those expected in biological material. The two curves thus calculated for situations *B* and *D* respectively are illustrated in Fig. 2. The asymmetry in the exponential case, although still present, is less marked, and differentiation in practice is unlikely.

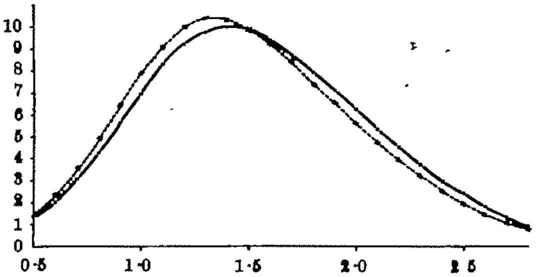

Fig. 2. —, linear *S.D.* 30 per cent; – – –, exponential *S.D.* 30 per cent

In making comparison between these theoretical curves and distributions observed in practice the absolute values of the abscissæ have no significance, only their relative variation. Therefore, to facilitate matching with experimental curves, all the theoretical curves have been re-drawn with linear ordinate scale and a peak value of 10, and with a semilogarithmic abscissa scale along which the curves can be moved without changing their shape.

Experimental Examples

Autoradiographs were prepared from smears of (*a*) human bone marrow cultures after two hours incubation with iron-59, (*b*) human leukæmic lymphocytes after three hours incubation with methionine sulphur-35, and (*c*) mouse thymus imprints 30 min. after administration of thymidine labelled with hydrogen-3. The autoradiographs were exposed long enough to give a mean grain count of 30–50 grains per labelled cell (the optimum grain count depends on the size of the cell and on the background), and grain counts were performed on 300–900 cells of the same type (that is, basophilic normoblasts, small lymphocytes, large thymocytes).

As only a limited number of cells was counted in each experiment the grain count distribution curve obtained was, in general, not smooth. In order to provide a 'best' smoothed distribution the results were considered in ranges of grain count 1–10, 11–20, etc. For each group the total number of cells was plotted against the actual mean value of grain count for that group. For comparison with the theoretical curves the final curve obtained was plotted on semilogarithmic paper with a peak (linear) ordinate of 10. Where more than 500 cells were counted it was still possible to obtain a smooth curve in this way considering ranges in grain count of 5, thus giving a more accurate form of the distribution.

In cases where the proportion of labelled cells in a population is significantly below 100 per cent, it is advisable to over-expose some slides to differentiate between the truly negative and 'false negative' cells. The latter may occur in populations with great ranges in uptake rate.

Caution is indicated with histological sections, as loss of parts of cells may affect the apparent range of uptake rates.

Figs. 3 and 4 show the experimental curve obtained with iron-59 in basophilic normoblasts (dividing population). It is clear that the iron-59 curve does not fit the normal distribution curve with 30 per cent *S.D.* (Fig. 3) but fits the exponential curve (situation *D*) remarkably well (Fig. 4). This, in conjunction with the early appearance of heavily labelled reticulocytes which is observed after a tracer dose of iron-59 (Suit *et al.* (1957); Lajtha and Oliver (1960)) is taken as indication of an exponentially increasing rate of

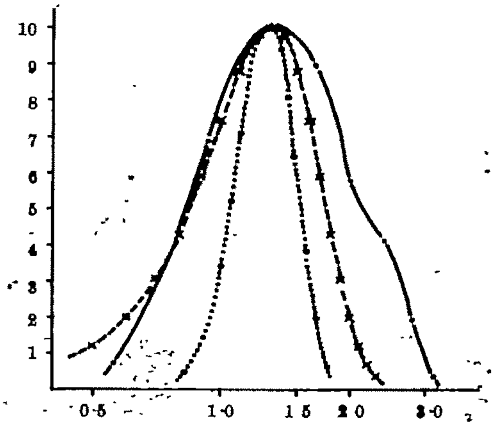

Fig. 3. · · · ·, Poisson (mean 45); – – –, normal (*S.D.* 30 per cent); ——, iron-59 experimental

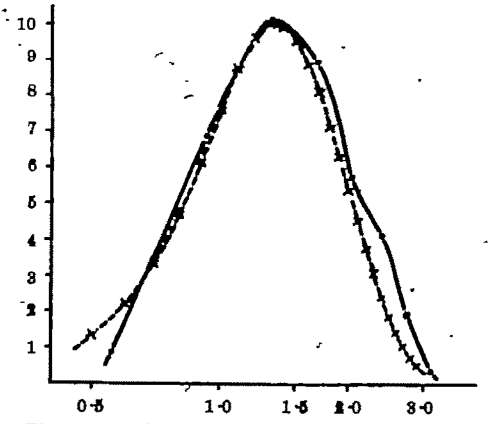

Fig. 4. ——, iron-59 experimental; – – –, exponential

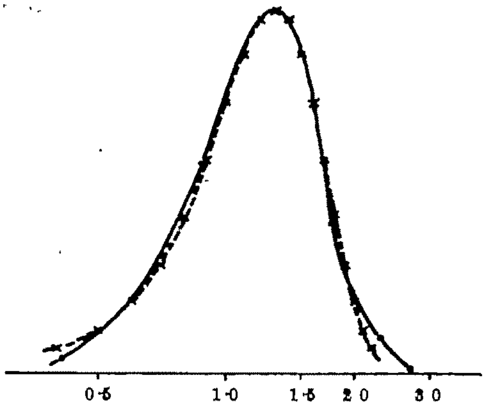

Fig. 5. ·—·, sulphur-35 methionine; ×---×, normal (*S.D.* 30 per cent)

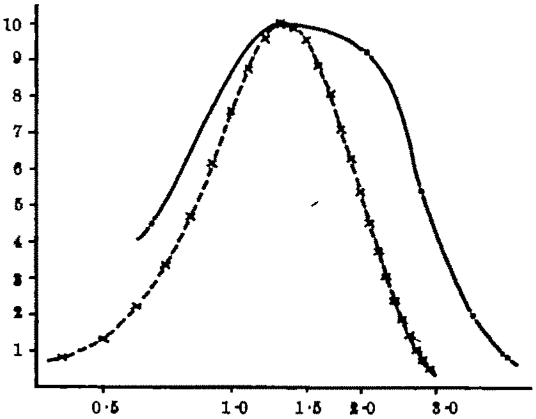

Fig. 6. ——, thymus deoxyribonucleic acid; ---, exponential

uptake of iron-59 (hæmoglobin synthesis) in the dividing population of basophilic normoblasts.

Fig. 5 shows the findings with methionine labelled with sulphur-35 in the small lymphocytes of human leukæmic blood. This experimental curve fits the normal distribution remarkably well, suggesting that the rate of methionine sulphur-35 uptake is constant (? turnover) in this apparently non-growing population of cells (these cells do not synthesize deoxyribonucleic acid).

An entirely different grain-count distribution curve is obtained with thymidine labelled with hydrogen-3 (a deoxyribonucleic acid label) in the large thymocytes (Fig. 6). This curve is considerably broader than the exponential increase from 1 : 2 ; in fact, it indicates a rate difference of the order of 1 : 5. On consideration this finding may not be unexpected ; even if synthesis of deoxyribonucleic acid proceeded at a constant rate along the length of every chromosome, there are significant differences in length between individual chromosomes. In a non-synchronized population of cells with 40 chromosomes (mouse), therefore, cells may occur in which at a given time all 40 chromosomes are in deoxyribonucleic acid synthesis, and others in which, for example, only the last ends of the longest chromosomes. Findings similar to that of Fig. 6 have been obtained with Ehrlich mouse ascites cells (thymidine labelled with hydrogen-3) as well as human bone marrow cells in which formate labelled with carbon-14 was used as deoxyribonucleic acid label (46 chromosomes).

Conclusions

The examples illustrated above indicate that autoradiographic grain-count distribution curves (coupled in some cases with content distribution curves) may be usefully employed in analysis of nature and rates of metabolic processes at the cellular level, information not easily obtained by other methods. Investigations with different labelled precursors in various normal and abnormal cells are in progress ; detailed results will be published elsewhere.

TERMINOLOGY IN PLANT- AND SOIL-WATER RELATIONS

By DR. R. O. SLATYER
Division of Land Research and Regional Survey, Commonwealth Scientific and Industrial Research Organization, Canberra

AND

PROF. S. A. TAYLOR
Department of Agronomy, Utah State University, Logan

AT the recent symposium on plant–water relations in arid regions, organized by Unesco at Madrid (*Nature*, 185, 435 ; 1960), the terminology currently used in this field aroused much interest. The following notes summarize the main points brought forward at a special discussion on this subject. Because of the interest created, the delegates suggested that these notes be published for the information, use and comment of all biological and physical scientists interested.

(1) The water relations of soils and plants have long been described by terms which are thermodynamic in nature, but which have usually been expressed in terms of equivalent pressures. This has led to what can be described as a 'hydraulic' terminology with the terms 'total soil moisture stress' (*TSMS*)[1] and 'diffusion pressure deficit' (*DPD*)[2] being the most common in soil and plant studies respectively. Alternative terms for diffusion pressure deficit, which are commonly used in Europe, include 'suction force'[3] and 'suction pressure'[4]. Alternative terms for *TSMS* include '*pF*' (ref. 5).

(2) While this terminology has frequently provided a satisfactory description of the phenomena observed, its value is limited for the following reasons :

(*a*) The use of pressure terms and units is misleading because in soil and plant systems situations normally exist where a high equivalent pressure or suction can be measured. However, this value represents a potential energy only and no water movement can be expected unless *gradients* of potential energy exist.

(*b*) With reference to the vacuolated plant cell the simple equation :

$$DPD = OP - TP$$

where OP is osmotic pressure and TP turgor pressure, has been in use for many years and has provided a useful interpretation of the cell-water relations of adult mesophytic leaves. Ideally, however, it only refers to a cell which is completely vacuolated. In many plants, the volume of cell wall can reach significant proportions and in xerophytic and sclerophytic tissue the volume of the vacuole can be less than one-half of the total cell volume. Accordingly, rigid use of this simple terminology can introduce errors and may prevent an accurate interpretation and description of the phenomena observed.

(c) Even though the most common terms in the present terminology—'total soil moisture stress' and 'diffusion pressure deficit'—are regarded as pressures and expressed in pressure terms, not only are they thermodynamic in nature but also they are measured by thermodynamic methods—for example, by measuring equilibrium vapour pressure or osmotic potential.

(3) Because of these weaknesses in the present terminology it is thought that a definite step forward would be achieved by adopting more basic thermodynamic terms and units which would enable all the factors contributing to the thermodynamic state of water to be adequately described and assessed. Both diffusion pressure deficit and total soil moisture stress are conceptually expressions of the Gibbs free energy of the water in plant and soil systems respectively. To this extent the reversion to thermodynamic terms and units is a simplification rather than a complication. Several authors, notably, Edlefsen[6], Edlefsen and Anderson[7], Broyer[8-10] and Taylor[11], have already suggested appropriate thermodynamic terminologies.

(4) The free energy function is considered to be the most appropriate thermodynamic function and the most appropriate term is considered to be 'water potential', that is, the chemical potential of the water in the plant or soil. Thus, water potential is the difference between the partial specific Gibbs free energy of water in the system under consideration and of free pure water at the same temperature (which is the reference state). There are several alternative methods for expressing water potential, as can be seen from the thermodynamic identity:

$$\Delta\mu_w = R_w T \ln a_w = R_w T \ln p/p_0 = V_w(P - P_0)$$

where $\Delta\mu_w$ is the water potential, R_w the gas constant per gram of water, T the absolute temperature, a_w the activity of water, p/p_0 the relative vapour pressure, V_w the specific volume of water and $(P - P_0)$ the pressure difference that can be associated with, for example, hydraulic head or turgor pressure.

(5) If we choose pressure (P) and mass fractions of water (n_w) and of solutes (n_j) as independent variables, the differential form of the Gibbs equation for the component water (μ_w) can be written for the homogeneous isothermal state as follows:

$$d\mu_w = \left[\frac{\partial\mu_w}{\partial P}\right]_{n_w,n_j} dP + \Sigma_j \left[\frac{\partial\mu_w}{\partial n_j}\right]_{P,n_w(n_j-1)} dn_j + \left[\frac{\partial\mu_w}{\partial n_w}\right]_{P,n_j} dn_w$$

where the subscripts outside the brackets indicate the variables that are held constant in the evaluation. The component $\left[\frac{\partial\mu_w}{\partial P}\right]_{n_w,n_j}$ is the specific or molar volume of water (V_w), and is found by plotting the change of μ_w with respect to changes in P for the water in the soil and plant system. It can be identified as the turgor pressure in plants or as hydraulic pressure in saturated soils. The component

$$\left[\frac{\partial\mu_w}{\partial n_j}\right]_{P,n_w(n_j-1)}$$

is the slope of the curve found by plotting water potential as a function of the concentration of one solute, with pressure, water content and all the other solute concentrations held constant. It is summed over all the j components to give a complete osmotic potential. Following the notation of Guggenheim (ref. 12, p. 207) the term is given the symbol $D\mu_w \left[= \Sigma_j \left(\frac{\partial\mu_w}{\partial n_j}\right)_{P,n_w} dn_j \right]$. This term is analogous to that of 'osmotic pressure' now in use. The term $\left[\frac{\partial\mu_w}{\partial n_w}\right]_{P,n_j}$ is the slope of the curve found by plotting the water potential μ_w against water concentration at constant pressure and solute concentration. This is the moisture retention curve and is associated with the soil moisture tension or soil suction as now used. The term will also describe the condition of water within the cell walls or the colloidal system of the protoplasm which cannot be accounted for by turgor pressure or osmotic potential. It is effectively measured as a 'water-release' relationship for plant tissue.

(6) As written, the above expression refers only to isothermal situations. If required, an entropy term can be introduced to permit description of non-isothermal situations:

$$d\mu_w = \left[\frac{\partial\mu_w}{\partial P}\right]_{T,n_w,n_j} dP + \Sigma_j \left[\frac{\partial\mu_w}{\partial n_j}\right]_{P,T,n_w(n_j-1)} dn_j + \left[\frac{\partial\mu_w}{\partial n_w}\right]_{P,T,n_j} dn_w + \left[\frac{\partial\mu_w}{\partial T}\right]_{P,n_w,n_j} dT$$

where T is temperature and $\left[\frac{\partial\mu_w}{\partial T}\right]_{P,n_w,n_j} = -S_w$, where S_w is the specific or molar entropy of the soil or plant water.

(7) Although the differential form of these expressions is more comprehensive and descriptive, the integral form is more straightforward and provides a more direct transition from the existing terminology. For example, one can write:

$$\Delta\mu_w = V_w \Delta P + D_x\mu_w + \int_1^{n_w} \tau . dn_w$$

when $\Delta\mu_w$ is the water potential, V_w is the specific volume of water, ΔP is turgor pressure or hydrostatic pressure, $D_x\mu_w = \int_0^{n_j} D\mu_w$ is the osmotic potential, and $\int_1^{n_w} \tau . dn_w$ is the matric (adjectival form of 'matrix') potential, τ is the slope of the water-release curve and n_w the water content expressed as a mass fraction, but which can be expressed in any concentration unit that is consistent with the units used for expressing τ.

Normally $\Delta\mu_w$ will be negative since the potential of soil or plant water is less than that of free pure water which is the reference. In plant and soil systems ΔP will normally be positive since turgor pressure and hydraulic pressure are usually greater than atmospheric pressure. In applications to unsaturated soil ΔP can be either positive as in the pressure membrane apparatus or negative as with water inside a tensiometer. The osmotic potential ($D_{\pi}\mu_w$) will be negative or zero since the concentration of solutes in soil or plant solutions is never less than in free pure water. The water content (n_w) will always be less than pure water since the soil or plant will dilute the water and the complete matric potential will be negative.

As systems become more complex and more independent variables are necessary to describe the status of water in the system; additional terms may be added to the thermodynamic equation to include the new variables. Likewise, external force fields such as those of gravity and electricity can be accounted for by adding terms to the equation (ref. 12, pp. 403, 410).

(8) While these expressions may appear more complicated than the more straightforward hydraulic equations, it is apparent that the same components can be identified and the same techniques can be employed in measurement. For example, the water potential ($\Delta\mu_w$) may be measured in plant tissues using the same methods as are at present employed for measuring *DPD* [8–10]. It may be measured in soil by determining the equilibrium vapour pressure of soil cores[14–16] or by measuring the several components separately and adding them together. The osmotic potential ($D_{\pi}\mu_w$) will be measured in plant systems in the same manner as the osmotic pressure of the cell sap is at present measured[13]. Likewise, it may be measured in soil systems by determining the osmotic potential of the extract at saturation and adjusting the value to actual soil water contents[16]. The hydrostatic or turgor pressure (ΔP) is not easily measured in plant tissues. In soils it is measured with piezometers. The slope of the water-release curve (τ) can be obtained by simultaneous measurements of $\Delta\mu_w$ and water content. This may be effectively obtained for soils by the use of pressure membranes, pressure plates or tensiometers that are permeable to solutes. Vapour pressure equipment[17,18] may also be used, providing adjustments are made for the solutes that are present. Weatherley and Slatyer[19] have described an effective method for plants.

(9) At present the most common units of expression are the pressure units of atmospheres or bars. In order to interpret these values in free energy units, it is desirable that a unit of similar numerical size be adopted. The unit of joules kgm.$^{-1}$ is suggested, although ergs gm.$^{-1}$ could be used without difficulty. One erg gm.$^{-1}$ is equivalent to a pressure of one dyne cm.$^{-2}$ multiplied by the specific volume of water (which is unity). The numerical conversion from units of pressure to units of energy may be made as follows:

$$1 \text{ atm.} = 1{\cdot}013 \text{ bars} = 1{\cdot}013 \times 10^6 \text{ dynes cm.}^{-2} = 1033{\cdot}2 \text{ cm. water}$$

$$1 \text{ joule kgm.}^{-1} = 10^4 \text{ ergs gm.}^{-1} \doteq 10^4 \text{ dynes cm.}^{-2} = 10^{-2} \text{ bars} = 1 \text{ centibar}$$

$$1 \text{ bar} = 10^6 \text{ dynes cm.}^{-2} \doteq 100 \text{ joule kgm.}^{-1} = 10^6 \text{ ergs gm.}^{-1} = 1019{\cdot}7 \text{ cm. water}$$

A GENETICALLY DETERMINED ENZYME IN THE PIG

By DR. K.-B. AUGUSTINSSON and DR. B. OLSSON

Institute of Organic Chemistry and Biochemistry, University of Stockholm, and
Department of Animal Nutrition, Genetics and Hygiene,
Royal Veterinary College, Stockholm

PIG blood plasma contains two esterases, an acetylarylesterase and a butyrylcholinesterase[1,2]. Both enzymes hydrolyse aromatic esters, for example, phenyl acetate, arylesterase being approximately 100 times more active toward this substrate than cholinesterase when hydrolysis rates are compared on a nitrogen content basis. In contrast to the activity of cholinesterase, the arylesterase activity exhibits considerable individual variation[2] with activity values ranging from 0 to 200. In previous reports[2,3] the values for arylesterase activity were expressed per 0·1 ml. plasma (instead of 0·02 ml., as in this communication) and were not corrected for cholinesterase activity. These values, therefore, are not directly comparable with those given above; they may be recalculated, however, by dividing previous values by 4 and subtracting with 10, which is the mean activity value per 0·02 ml. plasma for cholinesterase hydrolysing phenyl acetate.) These values were obtained with whole plasma and phenyl acetate in the presence of prostigmine, which selectively inhibits cholinesterase. Plasmas from all new-born piglets so far studied had very low activity in hydrolysing phenyl acetate. We have recently demonstrated[3] that the low activity at birth and also of certain adult animals is almost entirely due to cholinesterase, and is not due to the presence of an inhibitor. Previous experiments also demonstrated that the increase in plasma arylesterase activity of some piglets during the first weeks of life runs parallel with the increase in plasma albumin concentration, and that this increase in activity is gene-controlled. It was not possible, however, to explain how the various activity-levels are genetically determined and/or which type of gene interaction is most likely.

The results obtained recently in work with a great number of cross tests, including back-crosses, with pigs of various phenotypes have confirmed our proposal that the synthesis of plasma arylesterase is genetically controlled and made it possible to put forward the following hypothesis for gene interaction in the formation of this enzyme. The various phenotypes of adult animals are produced by the interaction of multiple allelic genes:

Allelic gene	Activity-level
a	0
A_1	25
A_2	50
A_3	75
A_4	100

Each allelic gene determines a certain plasma arylesterase activity and the distinguishable phenotypes among adult animals (at least two months of age) are produced as the manifestation of additive effects of two allelic genes, for example:

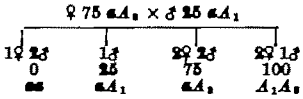
Genotype	Phenotype
aa	0
aA_2	50
A_1A_1	50
A_1A_3	100
A_3A_4	175

This hypothesis is strongly supported by the experimental results obtained, as will be briefly reported in the following. A full report will be published in *Hereditas*.

Matings were performed with animals of both Swedish Landrace (*Svensk lantras*) and Yorkshire breeds. No differences in gene interaction for the synthesis of plasma arylesterase have been observed between these breeds, pure or mixed. There is no sex influence upon this synthesis.

In our first experiments the phenotypes could be divided into three groups, corresponding to the esterase activities 75, 25 and 0. One sow from each group of the offspring obtained after crossing a boar of phenotype 0 (zero) with sows of various phenotypes was used in back-cross tests. A sow of phenotype 100 segregated into two phenotypes, 75 and 25. In back-cross tests, sows of either of these phenotypes again segregated into two groups, 75 and 0, and 25 and 0, respectively. It was concluded that the father was homozygous for the gene a responsible for 0 (zero) activity and that two allelic genes, A_3 and A_1, determined the activity of phenotypes 75 and 25, which consequently corresponded to the heterozygous genotypes aA_3 and aA_1. Similar results were obtained in matings with sows of phenotype 50 (genotype aA_2) and the same father. These experiments supported the hypothesis that four allelic genes produced the various phenotypes.

In order to obtain further evidence for the hypothesis, the progeny of a great variety of types of mating was studied. In all matings where both parents were of phenotype 0, the offspring were always of this same phenotype. When two sows of the same phenotype 100 were crossed with the same boar of phenotype 0 (genotype aa), the offspring in the two matings differed. There were two phenotypes (75 and 25) in one litter and only one (50) in the other. This means that the first sow was heterozygous for the genes A_3 and A_1, and the other sow homozygous for A_2. When both parents had the same plasma arylesterase activity (75), three phenotypes were obtained in the offspring in accordance with Mendelian inheritance. It was easily concluded that the genotype of both parents was aA_3 and the three phenotypes of the offspring corresponded to three kinds of genotypes, A_3A_3, aA_3 and aa. The offspring of a boar of phenotype 25 crossed with a sow of phenotype 125 segregated into three phenotypes, one of which (75) could correspond to two genotypes, aA_3 or A_1A_2. The existence of a series of multiple allelic genes was also supported by the observation of four phenotypes in the progeny of mating a boar of phenotype 125 and a sow of phenotype 100, the genotypes of which were A_2A_3 and A_1A_3, respectively. A similar segregation was obtained in the following mating:



In the series of mating performed, three various genotypes, A_1A_3, A_2A_2 and aA_4, were observed producing the same phenotype 100. These and a number of similar results strongly support the hypothesis that the biosynthesis of plasma arylesterase in adult pigs is genetically determined, and that the activity of this enzyme is the manifestation of additive effects of allelic genes.

The biochemical reactions determining this genetically controlled esterase activity are unknown. It has been demonstrated that the variation in activity is not due to the presence of activators or inhibitors. The various activities observed may be due to the same enzyme protein, the concentration of which varies or the specific activity of which is different in various phenotypes. The first explanation is the more likely, since it would be difficult otherwise to explain the rise in activity for certain groups in a litter during the course of lactation and also the various activity-levels observed. A third possibility is that the various activity-levels are due to the presence of different enzyme molecules of various turnover numbers, but this explanation seems unlikely for the same reasons. No differences in properties of the activity of various phenotypes have been observed. We therefore conclude that the various activity-levels found experimentally actually reflect various concentrations of the same enzyme protein, the synthesis of which is genetically determined by a series of multiple allelic genes. This synthesis is probably enzymatically controlled, and the activity of the enzyme(s) involved is (are) directly influenced by gene action.

We have no explanation so far as to the mechanism underlying the formation of the series of allelic genes. The existence of multiple activity-levels makes likely the occurrence of duplicate, triplicate and quadruplicate genes, corresponding to the allelic genes A_2, A_3 and A_4. This means that these alleles are to be regarded as the result of duplication, etc., of gene A_1 at the same locus in the chromosome.

This investigation has been supported by grants from the Swedish Medical Research Council. We are grateful to Prof. A. Hansson and Dr. S. Skårman, Animal Breeding Institute, Wiad, Sweden, for permission to use the livestock of that Institute.

ASTROPHYSICS

The Solar Flare of June 1, 1960

A SOLAR flare in the 3^+ category of importance and of exceptionally large extension was observed on June 1 at the Royal Greenwich Observatory, Herstmonceux, and at a number of other solar stations in Europe. We have recently been analysing the film in *Hα* light taken with the Lyot heliograph at the Royal Observatory, Cape of Good Hope, which gives a complete record of the flare at 1-min. intervals under cloudless conditions.

The spot group over which the flare occurred was of complex *E*-type containing 24 spots and had extended rapidly in area since its first appearance on the east limb on May 29. The flare began at 0823 U.T. and developed rather slowly until about 0837 when the 'flash' phase occurred with a rapid increase in area and intensity at the main centre (N., 30° lat.; E., 50° long.). The greatest extent of the emission filaments was recorded at about 0900 (Fig. 1) when the measured area was 27 (unit = 1 sq. degree heliographic at the centre of the solar disk). If we correct for foreshortening, the heliocentric angle (*h*) being 54°, we obtain a corrected area of 46 square degrees, or 2,230 millionths of the hemisphere, which makes this flare one of the largest observed in recent years and comparable in area with that of July 25, 1946.

From the measured co-ordinates we have replotted the shape of the flare as it would have appeared had it been seen on the Sun's central meridian. The emission filaments in this way can be seen to extend across the spot group in a north-east – south-west direction for a distance of 290,000 km., and some of the isolated outlying bright regions were located 200,000 km. to the south of the main centre.

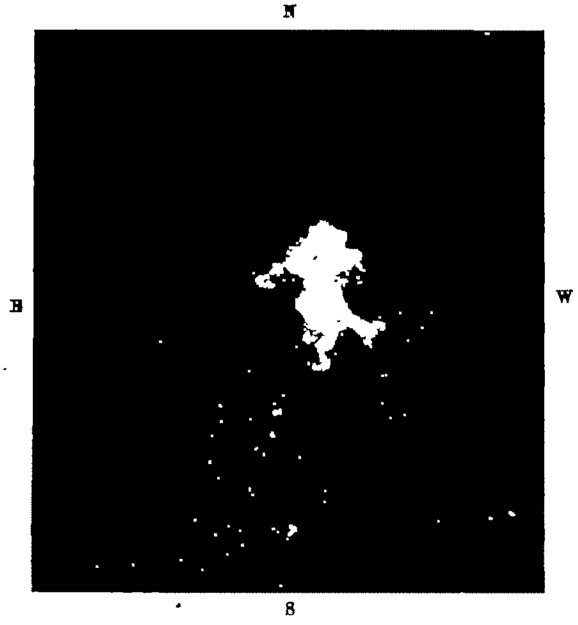

Fig. 1. Class 3^+ flare of June 1, 1960 (0900 U.T.), recorded with the Lyot *Hα* heliograph at the Royal Observatory, Cape of Good Hope

The Tatsfield Receiving Station of the B.B.C. (engineer-in-charge, H. V. Griffiths) reported a very severe sudden ionospheric disturbance occurring from 0837 until 1200, absorption remaining greater than normal until about 1400. In the peak period about 0900 all communications at high frequency were affected.

In the geomagnetic field a sudden commencement was recorded at 1800 on June 3, and this was followed by a minor storm (K_p max. = 7) lasting for two days. However, the distance of the flare from the Sun's central meridian reduced the probability that a magnetic storm would follow, and the long time interval between the flare and the sudden commencement, s.c. (57 hr.), suggests that this particular storm was caused by particles emitted from a subsequent flare.

A fuller account of the flare will be published elsewhere with accompanying light-curves. We wish to express our thanks to the staff at the Royal Observatory, Cape of Good Hope (under Prof. R. H. Stoy), for the fine film record; J. Churms, in charge of the Lyot heliograph, assisted by Mrs. E. Fiamingo, J. D. Laing, R. Lake and D. S. Malan.

Effect of Upper Atmosphere Wind on the Rotation of Satellite $1958\delta 1$

CHANGES in the rotation of $1958\delta 1$ (*Sputnik* 3 rocket) can apparently be explained by, and give additional evidence of, strong westerly wind in the upper atmosphere. According to Merson, King-Hele and Plimmer[1] such air-flow, accompanying the Earth's rotation, accounts for observed effects in the movement of the orbital planes of satellites.

The rotation period of $1958\delta 1$, estimated from its regular fluctuations of brightness, increased at a decreasing rate, from just over 8 sec. in June 1958, to about 9·5 sec. in mid-November. It then decreased by at least 0·3 sec. during the last few days of flight, as noted, for example, by Carr, Stewart and Senne[2]. Late in July 1958, the rate of increase decreased significantly. This effect is mentioned by Esipova and Zverev[3]. It coincided with entry of the perigee into denser tropical atmosphere; King-Hele and Walker[4] found a change in the rate of decay of the orbital period at this point.

Air resistance at perigee alone would be expected to exert a progressively increasing deceleration of spin. The observed behaviour reveals an opposing acceleration, which increased with the air density at perigee, and in the end became dominant.

Esipova and Zverev determined from visual observations that the rotation axis was transverse to the rocket axis, giving end-over-end tumbling. Since the observed 'flash period' always increased slightly with increasing flight range of observation, the rotation was retrograde with respect to the west-to-east transits observed and, therefore, clockwise as viewed from the north.

Such rotation would be most sensitive to accelerating 'windmill' behaviour, generated by the cross-wind, when the satellite passed northwards through perigee in the relatively dense and fast circulating tropical atmosphere. This condition would apply from late July 1958 onwards, and the effect is likely to have increased considerably when the altitude decreased shortly before fall-in.

Each feature of the rotation thus appears to be accounted for, perhaps more convincingly than in terms of meteorite impact, material ablation or even forces of electrical or magnetic origin. It may be that only very long, light-weight objects such as cylindrical balloons and empty rocket cases will show this type of response.

RADIOPHYSICS

Possibility of detecting Ionospheric Drifts from the Occurrence of Spread *F* Echoes at Low Latitudes

DURING the course of an investigation concerning the geographical extent of the scattered and diffuse echoes frequently observed during the night hours at high and low magnetic latitudes (spread *F*) an interesting phenomenon was observed. Times of occurrence of spread *F* echoes on ionospheric soundings taken every 15 min. during September and October 1957 at four stations in Peru (Talara, Chiclayo, Chimbote and Huancayo—average separation about 350 km., magnetic dip from 2° to 13°) strongly suggested that the patches of irregularities thought to be producing the spread *F* were often observed successively at each of the four stations. For example, an occurrence of spread *F* might be observed to begin at, say, 0015 hr. at Talara, the north-westernmost station, at 0045 at Chiclayo, at 0100 at Chimbote and at 0145 at Huancayo, the south-easternmost station. This tendency was particularly marked for the relatively short occurrences (less than about 2 hr. in duration) that were commonly observed during the latter half of the night. As the stations were located approximately along a straight line, it is not possible to deduce unambiguously the magnitude and direction of the suggested drift. It has been shown, however, that the geographic north–south component of the night *F* region drift is usually small at these latitudes[1]. Therefore, on the assumption that the drift was wholly in the magnetic east–west direction, magnitudes of the geographic east–west component of the apparent drifts indicated by the spread *F* occurrences during September and October have been estimated. A mean apparent drift velocity of 135 m./s. towards the east was obtained for period 0000–0400 hr. Skinner, Hope and Wright, using the Mitra technique at another equatorial location (Ibadan) during the same period, observed a mean east–west component of *F* region drift of about 110 m./s. towards the east[2]. The degree of agreement suggests that drifts, either of the patches of irregularities giving rise to the spread *F* echoes or of the disturbance producing the irregularities, may play an important part in the occurrence of spread *F* at low latitudes.

A more comprehensive study of spread *F* occurrences along the Peruvian chain of stations during the International Geophysical Year period, including a full interstation correlation analysis, is now being completed and will be published elsewhere.

PHYSICS

Thermal Expansion at Low Temperatures

CONSIDERABLE experimental data have been published[1] on the heat capacity C of solids, extending to temperatures which are very low in relation to their characteristic temperature θ; data are available in the temperature region $T \sim \theta/100$, where the Debye continuum model may be expected to apply and where for metals the electronic contribution is important. Complementary information regarding the thermal expansion coefficient, α, is desirable as it would throw additional light on the lattice dynamics of solids, particularly the anharmonic nature[2] of the interatomic forces as evidenced by the Gruneisen parameter $\gamma = 3\alpha\chi V/C$ (χ = incompressibility, V = volume). Also any data obtained about an electronic expansion coefficient, α_e, in metals should provide useful information about their band structures.

Unfortunately, most methods of measuring the expansion, whether by X-rays[3], interferometry[4] or capacitance[5], have not been sufficiently sensitive to trace its variation much below $\theta/10$. However, there are now available techniques for the accurate comparison of small capacitances which allow movements as small as 10^{-9} cm. to be detected, and these may be used to determine expansion coefficients down to $T \sim \theta/100$. Such techniques depend on the use of three-terminal capacitors in which the capacity to be measured is a mechanically well-defined gap between two of the terminals (or conducting surfaces) and the third terminal is a conductor which acts both as a guard ring and as a shield surrounding the other two. This unknown capacitance is then compared with a reference capacitance in a four-arm bridge of which the two other arms are tightly coupled inductive arms; ground-lead capacitances do not appear in the balance equations but merely affect the bridge sensitivity. Some recent developments in precise capacitance measurement have been described by Thompson[6] and their application to measuring thermal expansion will be described elsewhere[7]. The measurements described here on the thermal expansion of copper and iron were made with a capacitance-bridge kindly loaned by Mr. A. M. Thompson, of the Commonwealth Scientific and Industrial Research Organization Division of Electrotechnology.

An expansion 'cell' was made from O.F.H.C. copper (plus brass screws and mica insulating washers) which is a cylinder about 6 cm. long and 5 cm. diameter; in it is mounted a bobbin-shaped specimen of 5-cm. length with parallel lapped faces of 2-cm. diameter at each end. One end is fixed and the other (free) end-face forms a parallel-plate condenser with a 1·3-cm. diameter copper plate distant about 0·02 cm. Variations in the relative length of specimen and copper cell alter this 0·02-cm. gap and hence alter its capacitance. With our present bridge sensitivity of 10^{-6} *pF*, the 5 *pF* capacitance formed by this gap may be measured to 1 in 5×10^6, corresponding to $0{\cdot}5 \times 10^{-8}$ cm.; this amounts to about 1 part in 10^9 for a system of length 5 cm.

The expansion cell is mounted in a conventional cryostat[3] so that its temperature may be varied from 1·2° to 300° K. Thus far, most measurements have been confined to the region below 25° K. on specimens of (A) annealed O.F.H.C. copper, (B) sintered beryllium, kindly supplied by the Australian Atomic Energy Commission through Mr. G. L. Hanna, of its Metallurgy Section, (C) annealed 99·96 per cent iron, kindly supplied by the British Iron and Steel Research Association. Hence data have been obtained on the relative changes in length of (A) copper versus copper, (B) copper versus beryllium, (C) copper versus iron.

For system (A) the variation of gap with temperature is very small, confirming that the cell is mechanically stable.

For system (B) the relative measurements on copper–beryllium give values of the expansivity of copper if α(beryllium) $\ll$ α(copper). At low temperatures ($T < \theta/10$) we expect this to be true, at least for the lattice vibrational contribution, α_g, since to a first approximation:

$$\alpha_g(\text{beryllium})/\alpha_g(\text{copper}) \simeq C_g(\text{beryllium})/C_g(\text{copper}) \simeq [\theta(\text{copper})/\theta(\text{beryllium})]^3$$

and θ(copper) is more than three times smaller than θ(beryllium); here C_g is the lattice component of the specific heat. It appears partially confirmed by our data which then yields $\alpha = 0{\cdot}59_5 \times 10^{-6}$ per deg. C. as compared with a value $\alpha = (0{\cdot}58 \pm 0{\cdot}04) \times 10^{-6}$ per deg. C. obtained by Rubin *et al.*[4] at 25° K., their lowest temperature. However, this does not preclude beryllium from exhibiting a small electronic coefficient α_e, proportional to temperature (rather than T^3 as for α_g), which may be important in the evaluation of our results below 5 or 10° K. Concerning α_e, Visvanathan[5] has deduced theoretically that the electron gas should be responsible for a thermal expansion coefficient given by $3\alpha_e = aC_e/\chi V$, where C_e is the electronic heat capacity. The numerical constant a (sometimes denoted γ_e) should be 2/3 for a free electron gas, and for copper this leads to $\alpha_e \simeq 1{\cdot}5 \times 10^{-10}\,T$ per deg. C.; for beryllium it would lead to about half this value for α_e if the assumption $a = 2/3$ were true.

Assuming the expansivity of beryllium to be negligible, the data on system (B) give the following results for copper:

(1) No evidence of change in length greater than about 1 Å. could be detected between 1 and 4° K. If we assume that $\alpha = \alpha_e + \alpha_g = AT + BT^3$, then this limits the term $\alpha_e = AT$ to be not greater than $2 \times 10^{-10}\,T$ and the second term to $3 \times 10^{-11}\,T^3$. Theoretically α_e should be slightly less than this limiting value and may be partially masked by a similar term in beryllium.

(2) Analysis of the changes in length observed in the region from 4 to about 9 or 10° K. indicated that $\alpha \simeq (3{\cdot}0 \pm 0{\cdot}3) \times 10^{-11}\,T^3$ per deg. C.

(3) Two sets of values for the Grüneisen parameter were calculated as follows: a value γ_T(total) $= 3\alpha\chi V/C$, where $C = C_e + C_g$ and a value γ_g(lattice) $= 3\alpha_g\chi V/C_g$. Values of γ_T were sensibly constant at $1{\cdot}85 \pm 0{\cdot}05$ down to about 12° K. but fell rapidly below that, reflecting the apparent absence of any linear term in α to counterbalance the linear term in C. However, γ_g remains fairly constant to the lowest temperatures. Below 10° K., values $\gamma_g = 1{\cdot}9 \pm 0{\cdot}2$ follow from the relation $\alpha = (3{\cdot}0 \pm 0{\cdot}3) \times 10^{-11}\,T^3 = \alpha_g$ and the established data that $C_g = 1946\,(T/345)^3$ j/g mole deg.

For the system (C) of iron versus copper, changes in length were observable down to 1·5° K. These were approximately proportional to T^2 at the lowest temperatures, corresponding to an expansion coefficient varying as T. Above 4° K. they were corrected for the expansion of copper using data obtained on system (B). Results may be summarized for iron as follows:

(1) Below 8° K., $\alpha \simeq (0{\cdot}26 \pm 0{\cdot}04) \times 10^{-8}\,T$ per deg. C.; assuming that this linear term is the electronic coefficient α_e, then we find that $a = \gamma_e = \alpha_e\chi V/C_e \simeq 1{\cdot}7$.

(2) Between 8° and 15° K., results can be represented by $\alpha = 0{\cdot}26 \times 10^{-8}\,T + (1{\cdot}05 \pm 0{\cdot}1) \times 10^{-11}\,T^3$; if the second term is identified with α_g, then $\gamma_g \simeq 2{\cdot}0 \pm 0{\cdot}2$. Much of the uncertainty in the expansion coefficient above 8° K. arises because the correction for copper is substantial.

(3) Data obtained in the region 55–90° K. give values of γ_T ranging from 1·62 to 1·68 and measurements between 20 and 15° K. give $\gamma_T = 1{\cdot}8 \pm 0{\cdot}1$. These may be compared with a room temperature value of about 1·7.

Apart from taking further measurements on the system (C) between 10° and 50° K., it is hoped to: (a) obtain absolute values of α for copper using a different form of expansion 'cell' in which the specimen may be raised in temperature while the 'cell' is fixed at the temperature of a liquid bath. Such a cell has been completed and seems to work satisfactorily; (b) data for sapphire relative to copper in the existing 'cell' should also yield α values for copper since α for sapphire should be negligible at the lowest temperatures; (c) data on the electronic expansion coefficient for chromium and for palladium, (d) data for lead relative to copper between 1° and 10° K. where we should expect $\alpha_g(\text{lead}) \gg \alpha_g(\text{copper})$, and ($e$) data on the electronic expansion coefficient for the superconductors aluminium and niobium would be of great interest. Earlier measurements[10] of the change in dimensions of aluminium when superconductivity is destroyed by a magnetic field suggest that α_e should be surprisingly large; for niobium the large electronic heat capacity in the normal state and its high transition temperature make it an interesting study.

In conclusion, it appears from these measurements that iron exhibits a component of thermal expansion arising from the free electrons. In copper no such component has been found as yet although values for the Grüneisen parameter have been established down to below 10° K.

I am most grateful to my colleagues Messrs. A. F. A. Harper, W. R. G. Kemp and A. M. Thompson for their interest and advice.

Effect of Temperature on the Expansion on Setting of Gypsum Plaster

IT has been shown by Ridge[1] that setting-temperature exerts a profound effect on the structure of set gypsum plaster. He postulated that this change in structure would be accompanied by changes in other properties such as the expansion on setting. Experimental evidence showing the expansion of plaster on setting at different temperatures has recently been obtained. The observations were made incidental to the preparation of plaster samples of different pore sizes that were to be used as standard porous bodies.

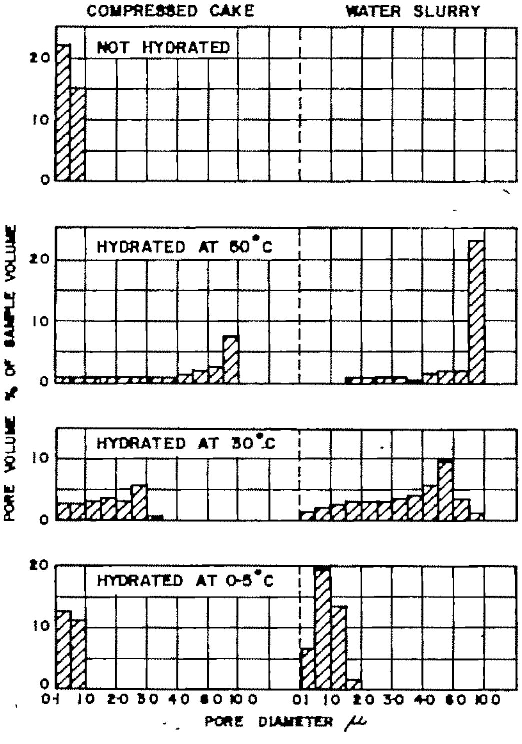

Fig. 1. Histograms for the pore-size distribution of plaster samples hydrated at different temperatures

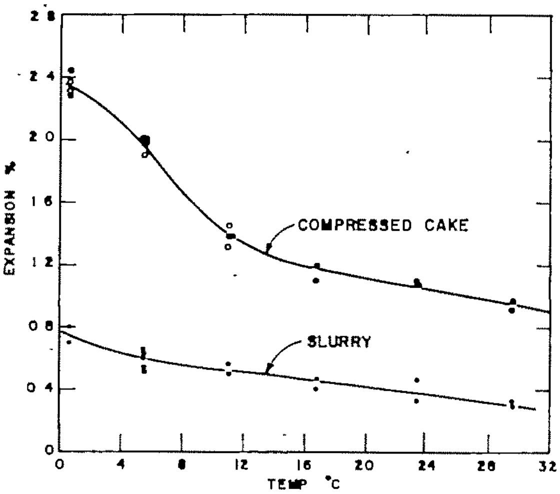

Fig. 2. Expansion on setting of plaster at different temperatures

A method was developed for compressing plaster of paris at a pressure of 5,000 p.s.i. into a cake which could then be hydrated at a desired temperature. The average pore size decreased as the temperature of set was decreased. This result confirms the observations made by Ridge[1] that crystal sizes decrease as the temperature of set is decreased.

Thus it has been found that by varying the temperature of set of plaster samples it was possible to vary their pore sizes over a wide range, as was also found by Ridge and Crook[2]. This was true whether the samples were made from a cake or water slurry of plaster of paris. Histograms for the pore-size distribution as obtained by a mercury porosimeter are given in Fig. 1. These results are for samples made from commercial unretarded plaster of paris. This plaster did not give reproducible results for expansion on setting.

Samples of pottery plaster compressed into cakes as well as mixed as water slurries in the ratio of 2 : 1 (plaster to water) were allowed to set at various temperatures. The expansion due to setting was measured with the aid of a travelling microscope. This expansion increased as the temperature of set was decreased. The results are shown in Fig. 2. The cake expanded about three times as much as the slurry for the same temperature of set.

The expansion on setting of plaster from a slurry was explained by Lea and Nurse[3] and Hill and Ridge[4] as being caused by the growth of crystals in contact. On this basis, when the conditions of setting are such as to lead to smaller crystals the chance of encounter with other crystals is greater, and expansion should be greater. It follows also that if the crystals are brought closer together initially the final expansion will be even greater for the same final size and shape of crystals. The greater expansion of the cake, which was about three times as much as that of plaster set from a water slurry at the same temperature, appears to confirm this. In the compressed cake the particles of hemihydrate are in actual contact, and expansion must begin as soon as hydration begins. In the case of the slurry, particles of hemihydrate are separated by water, and hydration can proceed for some time before encounter of the crystals occurs. In fact, a contraction is first observed when plaster begins to hydrate from a slurry.

The above results have practical significance in so far as they indicate the factors which control the expansion and pore-size distribution of setting gypsum plaster. Such information should be useful where control of these properties is essential.

I gratefully acknowledge the assistance of S. E. Dods, who carried out the laboratory experiment, and I also wish to thank B. M. O'Kelly for his helpful criticism.

Packing of Mixtures of Hard Spheres

We were pleased to see the recent communication[1] by E. B. Smith and K. R. Lea on their Monte Carlo calculation for mixtures of hard-sphere molecules. We are quite interested in this problem and have been trying to approach it experimentally by studying the random packing of mixtures of real macroscopic spheres.

When smooth spheres are poured into a container and lightly tamped, they assume a firmly packed disordered configuration. This corresponds, we believe, to the high-density limit of the disordered upper branch of the curve for the hard-sphere equation of state. In their machine computations on hard-sphere systems, Alder and Wainwright[2], and Wood and Jacobson[3], have found that an apparent phase transition to an ordered configuration usually occurs before the disordered configuration is tightly packed. By suppressing this transition, however, Jacobson and Wood were able to extend some of their Monte Carlo studies to disordered systems at the high-density limit[4]. We hope that Smith and Lea will also have an opportunity of investigating this limit in their calculations. We think it would be well worth while to check, whenever possible, how closely a few spheres with periodic boundary conditions actually behave like many spheres.

We have so far tested each of three different binary systems of 'Lucite' spheres at eleven different mixture ratios. We measure the piston displacements produced by successive pre-mixed 500-ball aliquots in each of five cylinders of various diameters. By extrapolating the average displacement volume to infinite cylinder diameter we eliminate surface effects. The results reported here have been digested from some 2,000 separate measurements.

In the three systems tested the contraction, or negative excess volume, was found to be approximately symmetrical:

$$V^{xs} \simeq -2A\,(V_1 + V_2)X_1X_2$$

where A is a dimensionless contraction factor dependent on the volume disparity, and X_1 and X_2 are 'mole' fractions. Even with our largest disparity, corresponding to a radius ratio of 1·6 : 1, there was no apparent asymmetry. By contrast, the calculations of McLellan and Alder[5] indicate a pronounced asymmetry at this radius ratio in low-density mixtures. The comparison is ambiguous, however, since their results also show that the asymmetry tends to vanish when the volume contractions are as small as those we have found.

Table 1

V_1 (c.c./ball)	V_2 (c.c./ball)	V^{xs} ($x = 0·5$, c.c./ball)	A
0·642	0·406	−0·003 ± 0·001	0·006 ± 0·002
0·646	0·266	−0·004 ± 0·001	0·009* ± 0·002
0·647	0·160	−0·012 ± 0·001	0·030 ± 0·002

The actual volumes of the spheres themselves were 0·408 c.c. for the larger component and 0·260 c.c., 0·1705 c.c. and 0·1032 c.c., respectively, for the smaller components. The packing volumes for the disordered pure components, as shown in Table 1, exceed the calculated close-packed volumes by 17·0, 16·0, 15·3 and 14·8 per cent, respectively, in very good agreement with the figure of 15(±3) per cent reported by O. K. Rice[6].

The apparent variation in volume of the larger component, V_1, is an artefact of the statistical analysis. If, as we suppose, it is due to a slight unacknowledged asymmetry in V^{xs}, it should be approximately linear in the volume disparity, δ (defined below), and should affect the volumes of the smaller components in an equal but opposite manner. Our values of A should not be affected at all by such an asymmetry.

We summarize our results by:

$$A \simeq 0{\cdot}019_5\,\delta^2$$

where $\delta = 2(V_2 - V_1)/(V_2 + V_1)$ is the dimensionless volume disparity. Since A must be an even function of δ which goes to zero at $\delta = \pm 2$, as well as at $\delta = 0$, our expression gives only the limiting behaviour at small differences of radii. We find no indication of a positive V^{xs} at small δ.

For larger differences of radii there are similar results reported by C. C. Furnas on mixtures of lead shot and other systems[7]. It would be interesting to see if Furnas's estimated shrinkages for arbitrary fractional void contents in static systems are anything like the results one calculates for dynamic systems with the same voidages.

Radioactive Labelling of Membrane Filters for the Assay of Air-borne Material

The quantitative assessment of air-borne material with membrane filters is being widely employed, mainly because of their high collection efficiency, non-hydroscopic properties and more uniform particle deposition than on other filter materials[1]. Since most of the particles deposited are held at the surface[2], the classical methods of assessment of deposits can be replaced or augmented by indirect methods. The latter consist, for example, in estimating the amount of deposit material by comparing stains[3] with suitable

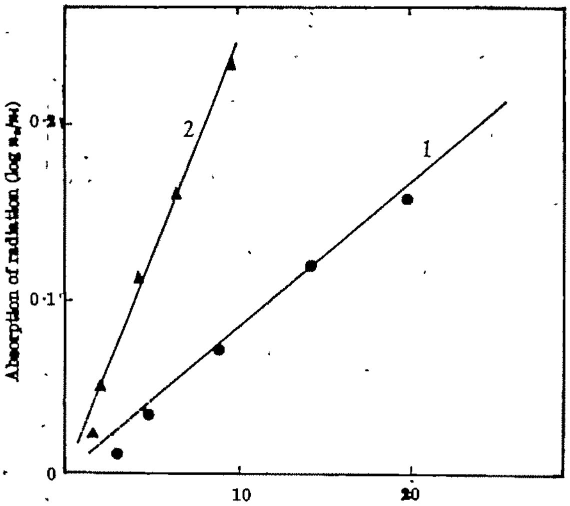

Fig. 1. Relation between β-ray absorption and thickness of dust layer. Curve 1, filters labelled with thallium-204; curve 2, filters labelled with nickel-63

standards or by objective measurement as, for example, reflectance photometry[4]. Chemical reaction between suitably impregnated or wetted filters and aerosol droplets may also be employed with quantitative estimation of the resulting colour effects[5].

It is known that various substances may be incorporated into the filter mass by adding suitable reagents to the stock solutions used for filter preparation[6]; thus it is possible to obtain filters containing chemical reagents in the form of very fine and homogeneous dispersion throughout the filter. Such reagents may react with aerosol droplets or with the surface layer of solid particles.

The application of radioactive thickness gauging for the estimation of deposit mass in filters has already been reported[7]. The present communication deals with the application of special features of membrane filters by converting the filters themselves into the radiation source used for thickness gauging, thereby eliminating the effect of filter thickness from measurement.

Although the incorporation of radioactive material into the filter mass is an evident procedure and will be reported in due course, initial work was performed by adsorbing radioactive nickel or thallium salts from solution upon the filter surface. The filters used had a mean pore size of $2r = 0·9\mu$ and a thickness of 130μ. The diameters of the filter disks were 36 mm. Initial total filter activities were 0·1–0·2 μc. and 1–5 μc. for thallium and nickel filters, respectively.

Filters of this kind were used for the estimation of the concentration of solid aerosols and industrial dust of constant composition. Prior to air filtration, initial filter activity was measured with a Geiger–Müller window counter (3·7 mgm./cm.^{2}) (activity n_0). Thereafter air was drawn through the filter, and as soon as a visible layer had formed on the filter, filtration was interrupted, residual activity measured and the mass of the deposit determined by weighing. This procedure was repeated several times and the expressions log n_0/n_i, where n_i are the residual activities, calculated. These values were correlated with the amounts of deposit per unit filter area.

Fig. 1 illustrates a typical example with flue dust of mean particle size $1·7\mu$, the chief chemical components of which were alumina, ferric oxide, silica and traces of other components. Experiments summarized in Fig. 1 were performed with filters labelled with nickel and thallium.

Results indicate that the preparation of homogeneously labelled filters and measurement therewith are possible. Such filters may be used for the rapid assessment of air-borne material. The lower limit of sensitivity is at present found to be 1·6 mgm./cm.^{2} and 6·0 mgm./cm.^{2} for filters labelled with nickel and thallium, respectively. Because of their weak radiation and long half-lives, nickel filters seem to be the more suitable ones. With an effective filter area of 1 cm.^{2}, absolute air volumes of 10–300 litres are sufficient to obtain deposits suitable for the assessment of high and medium dust concentrations.

It is evident that the present procedure provides mass-proportional values of dust concentration. More detailed investigation indicates that the sensitivity of measurement by the method outlined depends not only on the chemical composition of the assayed dust but also on its particle size distribution.

A more detailed account of this work will appear elsewhere.

RADIATION CHEMISTRY

Changes in Conductivity of Pure Water caused by X-Irradiation

Most of our present knowledge about the physicochemical processes occurring in the radiolysis of water has been obtained by purely chemical methods[1]. I have now tried to obtain some additional data by using a physical method. In the course of the primary and secondary processes which occur when water is irradiated with ionizing radiation, it is possible that charged particles will be formed which cause an increase in conductivity during irradiation. I therefore studied the variation with time of the conductivity of pure, non-degassed water when it was submitted to pulsed X-irradiation, in order to obtain information about the eventual concentration and life-time of such charged particles[2].

In a preliminary investigation, water, prepared by distilling three times—twice in a quartz still—with access of air, was irradiated in a conductivity cell made of 'Plexiglas' and with silver electrodes, with X-ray pulses (60 kVp., average dose-rate about 5 kr./min.) obtained by a rotating sectored disk.

A d.c. voltage was applied to the cell through a resistor, so that a periodical change in conductivity synchronous with the X-ray pulses would give rise

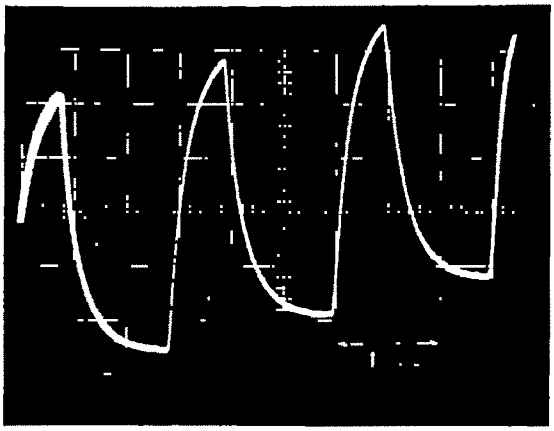

Fig. 1. Photograph of an oscilloscope picture showing the variation of conductance when water is irradiated with square wave X-ray pulses (light to dark period 1 : 2)

to an a.c. voltage with the same frequency. This voltage was measured by means of a synchronized amplifier. The synchronization was effected by interrupting the light beam falling on a photoelectric cell by the same sectored disk.

The experiment showed that there was in fact a periodical change in conductivity, the amplitude of which was inversely proportional to pulse frequency in the range from 10 to 3,000 c.p.s. covered in this investigation. It could therefore be concluded that during irradiation ions were formed with a life-time greater than 0·1 sec.

Based on these results, I constructed an apparatus with which I could display on an oscilloscope screen the variation with time of the conductivity of water irradiated with slow X-ray pulses (0·2–20 c.p.s.).

The water used in this experiment was pre-distilled first from alkaline permanganate and then from acid dichromate solution before being further purified in the quartz still, in order to be certain that no organic impurities were present. Between the two quartz distillation stages the vapour was heated to about 800° C. The conductivity cell, this time made of quartz and with platinum electrodes, was connected to an a.c. bridge operating at 2 kc.p.s. The diagonal voltage, which was proportional to the variation of conductance, was amplified, rectified, and fed to a d.c.-oscilloscope ('Tektronix').

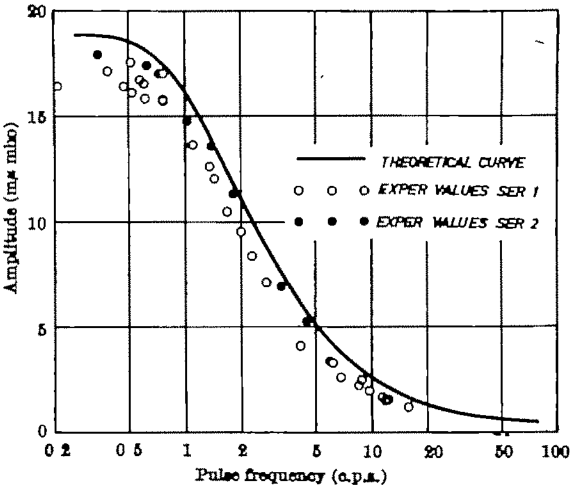

Fig. 2. Amplitude of the periodic variation of conductance as a function of pulse frequency. The theoretical curve is calculated from the experimentally obtained dose-rate dependence and life-time. Maximum dose-rate, 11·9 krads/min.

Fig. 1 shows a photograph of the oscilloscope picture showing the variation of conductance caused by irradiation with square wave-pulses (light to dark period = 1 : 2). In Fig. 2 the amplitude of the periodical conductance changes is plotted against pulse frequency. Two effects seem to be superimposed: (1) A reversible increase in conductivity during irradiation which returns to zero after the end of irradiation; (2) an irreversible rise in conductivity which starts practically instantaneously with irradiation and continues until the end of irradiation.

An analysis of the variation of conductivity as a function of pulse-frequency and dose-rate leads to the conclusion that the reversible effect may be due to the formation of ions the concentration of which varies according to the differential equation:

$$\frac{d[X]}{dt} = G_x \frac{\delta}{N_a} - k'[X][S] - 2k[X]^2$$

where $[X]$ is the concentration of the ions in question, $[S]$ that of a scavenger substance with which these ions can react monomolecularly, N_a the Avogadro number, δ the dose-rate, k and k' reaction constants, and G_x the yield of the ions formed.

A comparison of the properties of the observed ions with radiation-chemical data from the literature suggests that the ion X may be identical with the radical-ion $\cdot O_2^-$, that is, the anion of the radical $HO_2\cdot$ (ref. 3). If this is assumed and if the radical $HO_2\cdot$ is completely dissociated at the pH of the water investigated (5·5): $G_x = 4{\cdot}3$ radicals/100 eV., $k'[S] = 2{\cdot}9$ sec.$^{-1}$, and $k = 1{\cdot}45 \times 10^7$ litres/mole × sec. The radical-ion $\cdot O_2^-$ is, according to Hajssinsky[4], formed directly by the reaction of H-radicals with the dissolved oxygen:

$$H\cdot + O_2 \rightarrow H^+ + \cdot O_2^-$$

A more detailed discussion of a chemical reaction mechanism suggested leads to the equation: $G_x = G_H + G_{OH} + G_{HO_2} - 0{\cdot}4 = 4{\cdot}6$ radicals/100 eV. (with radical yields according to Allen and Schwarz[5]). Dainton and Rowbottom[6] have determined the recombination constant of the radical $HO_2\cdot$ as 3×10^6 litres/mole × sec. The difference between this value and mine (for $\cdot O_2^-$) might be explained by a difference in pH.

The irreversible effect observed in my experiment is probably due to the formation of percarbonic acid from the carbon dioxide dissolved in the water[7]. According to my experiment the yield of this reaction would be $G(H_2CO_4) = 0{\cdot}2$ molecule/100 eV. The term 0·4 in the equation for G_x mentioned above is twice this value.

A full account of this investigation will be published elsewhere.

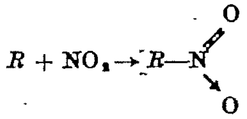
Radiation-induced Nitration of Aliphatic Hydrocarbons

THE behaviour of fission product iodine in a tributyl phosphate–kerosene system for reprocessing pile-irradiated uranium fuels has recently been studied in this laboratory. It was found that the principal mode of fixation of iodine in the hydrocarbon diluent was scavenging by hydrocarbon radicals produced by the action of the fission product radiation. However, it was observed that the G-value for fixation under process conditions was only about 0·1. This is very much lower than the values of about 7·0 reported for air-free n-heptane[1] and 5·6 for air-free *cyclo*hexane[2], which are generally accepted as giving some indication of the total yield of radicals in irradiated aliphatic hydrocarbons.

It was considered that other radical scavengers must be present in the process solutions in addition to the iodine. Atmospheric oxygen will certainly be at least partly responsible for the low uptake of iodine; but it was surmised that the nitrogen oxides, always present in radioactive nitrate solutions, may be more important in some cases. The oxides NO and NO_2 both have an 'odd electron' structure and are paramagnetic; they would therefore be expected to combine with alkyl radicals rapidly and with little activation energy requirement. To test this idea, n-dodecane containing 10 gm. NO_2/litre was irradiated using a 7·2-c. strontium-90 β-source. The mean radiation dose-rate was 2×10^{18} eV./ml. hr. and the duration of the irradiation was 114 hr. No special precautions were taken to exclude air. Infra-red spectral examination of the irradiated dodecane showed strong R—NO_2 (1,555 cm.$^{-1}$, 1,350 cm.$^{-1}$) and R—COOH (1,720 cm.$^{-1}$) bands. Slight absorption peaks at 1,680 cm.$^{-1}$ and 1,645 cm.$^{-1}$ were attributed to alkyl nitrite and alkyl nitrate, respectively. Comparison with standard substances showed that the G-value for R—NO_2, assumed to be nitrododecane, was 5·0. The yield of carboxylic acid, taken as dodecanoic acid, was about 1·0. No change could be detected in a dodecane solution of NO_2 which had been allowed to stand in the absence of radiation for a similar length of time. Carboxylic acid formation is presumably the end result of radical scavenging by atmospheric oxygen: in an earlier experiment, in which the dissolved NO_2 became exhausted, the yield of carboxylic acid was more than doubled.

These results are in good agreement with previous work on iodine scavenging in oxygen-free hydrocarbons[1,2] and suggest that one of the most important solvent degradation phenomena in highly active tributyl phosphate–hydrocarbon processes may be radiation-induced nitration. It is probable, in NO_2 solutions that are completely devoid of oxygen, that the only products arising from the alkyl radicals will be nitroalkanes together with small amounts of alkyl nitrites, the latter possibly arising from a reaction of alkyl radicals with excited NO_2 molecules:



$$R + NO_2 \rightarrow R\text{—}N\begin{smallmatrix} \nearrow\!\!\!\!= O \\ \searrow O \end{smallmatrix}$$

$$R + NO_2^* \rightarrow R\text{—}O\text{—}N{=}O$$

The radiation chemistry of aliphatic hydrocarbon–nitrogen oxide systems seems to be worthy of further study since information thus obtained should be of considerable value in elucidating organic radiation chemical mechanisms in general, and would provide a unique opportunity of obtaining unequivocal evidence regarding some of the fundamental processes proposed in contemporary theories of aliphatic nitration such as, for example, those reviewed by A. V. Topchiev[3].

Role of Oxygen in the Cross-linking and Degradation of Deoxyribonucleic Acid by Ionizing Radiations

WHEN deoxyribonucleic acid in dilute aqueous solutions is irradiated with X-rays, the attack by the free radicals produced in water leads to main-chain scission, and this reaction is essentially the same in the presence as in the absence of oxygen[1]. Irradiation of nucleic acid in the solid state and containing less than 25 per cent of water leads to a complex series of reactions which, judged by physico-chemical measurements, were largely unaffected by oxygen. With nucleic acid gels having a water content between these two extremes, oxygen was found to exert a pronounced influence on the changes produced by irradiation with 1-MeV. electrons. Since deoxyribonucleic acid is present in the cells in the form of a relatively concentrated gel, the response to radiation in this form is more likely to be of biological significance than the behaviour of dilute solutions or nearly dry solid.

The nucleic acid used in these gel experiments was obtained from salmon sperm, contained little salt (less than 3 per cent sodium acetate) and was free from protein (less than 0·02 per cent). Its molecular weight was 10^7 and its physico-chemical properties have been described in detail (see ref. 2). The molecular weight (determined by light-scattering) of nucleic acid in the dry or nearly dry state initially falls on exposure to 1-MeV. electrons to about two-thirds of its starting value and then increases again, while the intrinsic viscosity falls continually with dose. From these and other data, Alexander, Lett, Moroson and Stacey[3] concluded that irradiation produced branching and main-chain scission simultaneously, to approximately the same extent, so that the molecule becomes less asymmetric (that is, resulting in a fall of viscosity) without there being a substantial change in the average molecular weight.

By equilibrating the nucleic acid with air or nitrogen at different relative humidities, the water content (gm. of water per 100 gm. of polymer) was varied from < 0·5 per cent to 200 per cent. As the water content is increased above 25 per cent, main-chain scission with reduction in molecular weight becomes the predominant reaction of irradiation in air (see Fig. 1). When the gels are irradiated in the absence of oxygen, the molecular weight increases (see Fig. 1) until some of the nucleic acid has become so highly cross-linked that it no longer dissolves in dilute salt solution, but only swells. Fig. 2 shows that the formation of this insoluble network has a threshold, and the behaviour of 'wet' nucleic acid irradiated in the absence of air is typical of a cross-linking system such as polythene[4]. Once cross-linked gel begins to be formed, the molecular weight (because of polydispersity, it is probable that the molecular weights of the highly cross-linked samples are underestimated) of the soluble fraction falls because the largest units are preferentially linked into the insoluble fraction. This again is in accord with polymer theory[4]. The quantitative recovery of the insoluble nucleic acid is difficult, since after suspension in dilute salt solution much of it is present in a highly swollen form which can only be removed by high-speed centrifugation and the values obtained vary somewhat from experiment to experiment.

We interpret these results, which will be published in full elsewhere, by assuming that sparsely ionizing radiations produce reactive centres in the nucleic acid molecules which can combine with one another to give cross-links, or react with oxygen to give a product which can no longer develop cross-links (cf. ref. 5). The increase in the number of cross-links formed in the absence of oxygen by a given dose with increasing water content of the nucleic acid specimen we attribute to the greater mobility in wet samples of the polymer chains, and this promotes interaction between the active points. In nucleic acid, with less than 25 per cent of water, inability of active centres to meet hinders cross-linking.

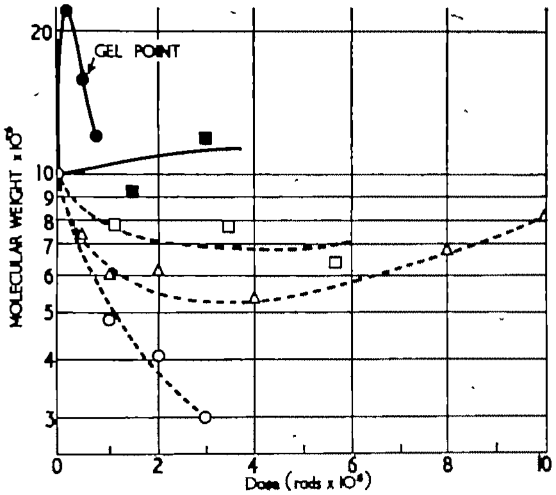

Fig. 1. Change in average molecular weight (measured by light scattering) of deoxyribonucleic acid fibres with different moisture contents after irradiation with 1-MeV. electrons under air and nitrogen

○, 100 per cent water content irradiated in air
●, 100 ,, ,, ,, ,, ,, ,, nitrogen (or vacuum)
△, 20 ,, ,, ,, ,, ,, ,, air
□, 0 ,, ,, ,, ,, ,, ,, air
■, 0 ,, ,, ,, ,, ,, ,, nitrogen (or vacuum)

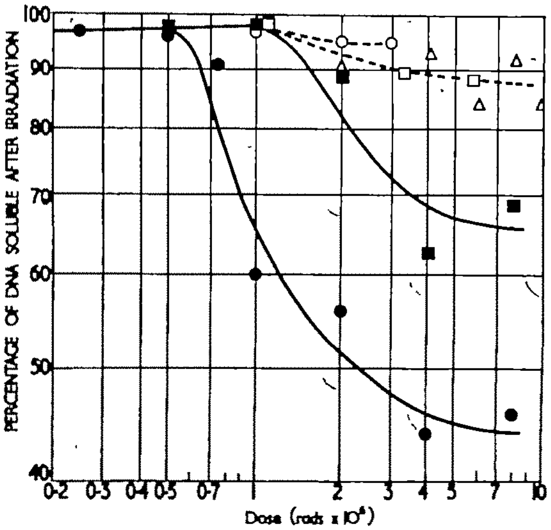

Fig. 2. Fraction of deoxyribonucleic acid rendered insoluble in M/100 sodium chloride (that is, removed by 6 hr. centrifugation at 20,000g). Symbols as in Fig. 1

In the presence of air, few cross-links are formed by direct action, and the degradation observed on irradiation of the samples containing an equal weight of water is due to direct action plus the attack by the radicals formed in the water. In the absence of oxygen, the active centres produced by direct action give rise to cross-links which exceed the number of main-chain scissions from the combination of direct and indirect actions, and therefore the net effect is an increase in molecular weight and gelation. Because the indirect effect produces only scission, there must, at a given dose under nitrogen, be a water content at which the amounts of scission and cross-linking are equal and above which gel is not formed. For a dose of 10^{6} rads this occurs at 300 per cent of water.

We wish to thank Mr. D. Moore of the Medical Research Council Experimental Radiopathology Unit for radiation facilities.

CHEMISTRY

Possible Discovery of Ion-Pairs by Interferometry

In the course of an investigation on electrodeposition to determine the cause of what Ibl and Muller[1] called an "anomalous maximum" near the cathode, and which O'Brien and Axon[2] independently noted and named the "second wave" in a complete, electrode-to-electrode interference pattern, it was found that this second wave does not develop in electrolyte solutions in which ion-pairs do not form. Such a solution is nickel sulphate[3], in which it has been shown that, presumably because of the strength of the bonds and lack of lability in the octahedral nickel aquo-complex, the closest approach of the sulphate ion cannot be less than the diameter of one water molecule (see Figs. 1 and 2). Electrolysis of a silver perchlorate solution gave the faintest traces of a second wave, which may be considered to be additional supporting evidence. Since Fajans and Luhdemann[4] have shown that free ions in solution may be expected to give higher refractive indices than ion pairs, and indeed a plot of concentrations versus refractive index of values taken from Landolt–Bornstein shows no deviation from linearity for nickel sulphate (which deviation is usually attributed to ion-pairs) until concentrations in the neighbourhood of 1 *M*, it follows that the cathode maximum may be explained by the dissociation of ion-pairs.

It was considered that the formation of ion-pairs was probably not an instantaneous process and that the electrodeposition cell being used was suited to a study of the kinetics of this process. The cell contains about 0·15 ml. of solution when the depth of the electrodes is 2 mm. and their separation 3 mm.

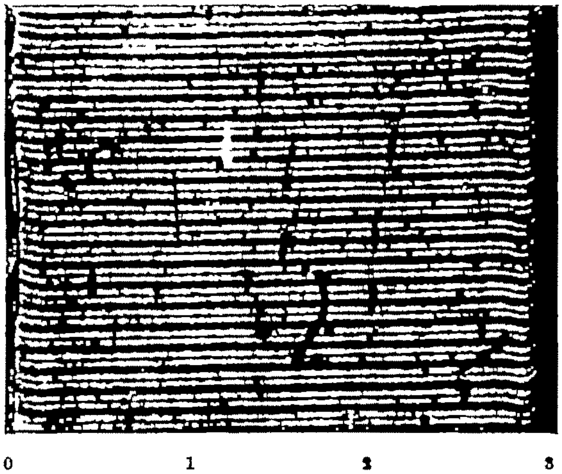

Fig. 1. 30 gm./l. copper sulphate, 3 mm. electrode separation, 2 m.amp./cm.^{2}, 10·8° C., 0 19700 V.

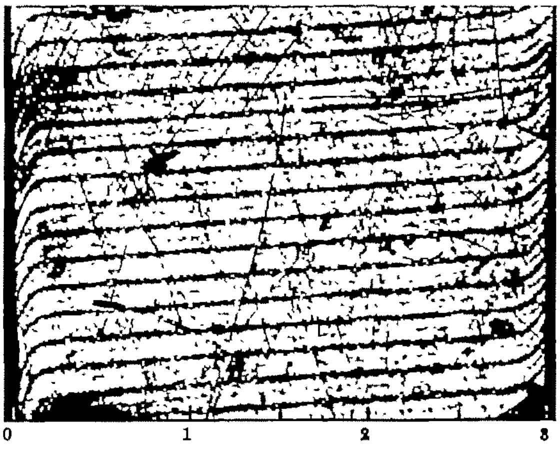

Fig. 2. 33 gm./l. nickel sulphate, 3 mm. electrode separation, 3 m.amp./cm.^{2}, 25 0° C., 2 0 V.

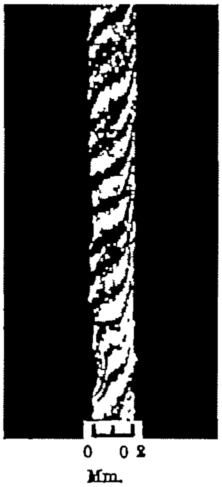

Fig. 3. 30 gm./l. copper sulphate, 0 2 mm. electrode separation, 2 m.amp./cm.^{2}, 9 8° C., 0 17221 V.

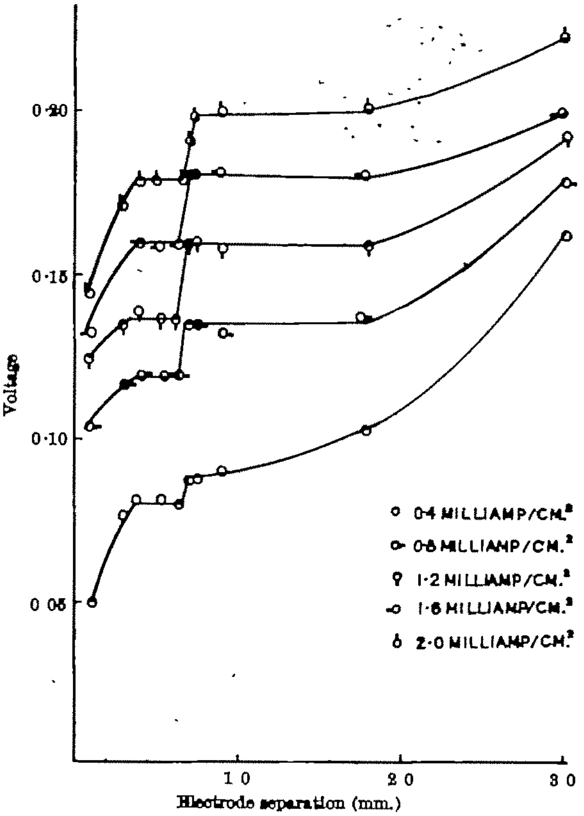

Fig. 4. Plot of voltage against electrode separation at several current densities

It can be calculated from the mobility of the ion (only Cu^{2+} need be considered as the cell is $Cu|CuSO_4|Cu$), which is about $1{\cdot}12 \times 10^{-3}$ cm./sec., that at 0·33 V. the time to traverse the 3 mm. of the cell is about 300 sec. The maximum of the second wave occurs at about 0·1 mm. from the electrode at both electrodes, and its amplitude has been found to vary directly as the current density[2], and the 'time of migration' to this distance should be 9 sec. Hence when the electrodes are placed so that the anode and cathode second waves overlap (Fig. 3), no second wave should form, and this was found to be so. But since there is the possibility that the effective dielectric constant of the solution is low and a change in field gradient might be expected, we do not place any special significance on the time of 9 sec.

When the electrodes were moved together at constant current density, a family of curves (Fig. 4) was found. The curves have the same features occurring at the same distance. A plateau where there is no apparent increase in total resistance with distance begins at about 0·37 mm. and ends at about 0·7 mm. in an abrupt, nearly vertical step.

It was expected that the distance at which the first plateau was found would vary with the voltage applied, since conventionally the speed of the ions has been considered to depend on this. This effect has not been found. The step height varies around about 0·02 V. while the expected height by Nernst's equation and thermodynamics from the dissociation constant of copper sulphate is 0·06 V.

Explanation of these and other aspects is being actively investigated, and greater precision of measurement is being sought.

Solid-Solid Interactions on Active Adsorbents

In recent years the diffuse spectral reflectance properties of various solid systems have been investigated[1,2], and several analytical applications have been developed[3-5]. Often it has been reported advantageous to mix the optically absorbing substance with an inactive powdered diluent such as sodium or potassium fluoride. When this is done the reflectance spectrum of the absorbing substance is sharpened and clarified in many cases. More pronounced effects have been obtained when a so-called active adsorbent powder such as chromatographic alumina or silica gel is substituted for the inactive diluent. In an attempt to study the nature of the changes brought about by active adsorbents in the solid state, pilot experiments have been carried out using Michler's ketone (4,4'-*bis*dimethylaminobenzophenone) mixed with active alumina. Michler's ketone has a well-defined absorption spectrum in transmittance in solution and reflectance from the solid, and is quantitatively removed from solution in a non-polar solvent by alumina. In a typical experiment 1 and 2 mgm. of the powdered ketone were mixed with 3 gm. of acidic and basic alumina (Woelm) and the solid mixtures allowed to stand for several days at room temperature in sealed containers. Visual changes slowly occurred in these systems until in appearance they were virtually identical with alumina on which the ketone had been adsorbed from a solution as in ordinary column chromatography. It is suggested that the two phenomena involve essentially the same adsorption process, differing only in rate.

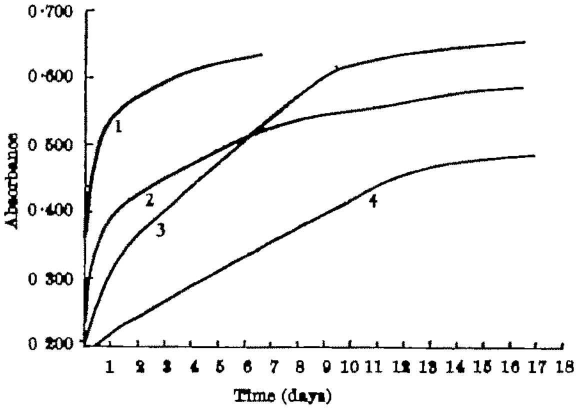

Fig. 1. Changes with time in the absorbance at the wave-length of the maxima of various mixtures of Michler's ketone and chromatographic alumina as measured by reflectance. 1, 2 mgm. ketone and 3 gm. acidic alumina; 2, 1 mgm. ketone and 3 gm. acidic alumina; 3, 2 mgm. ketone and 3 gm. basic alumina; 4, 1 mgm. ketone and 3 gm. basic alumina

The diffuse reflectance spectra of the Michler's ketone–alumina mixtures were measured at intervals as the solid–solid interactions were taking place. The instrument used was a Beckman model *DU* spectrophotometer with a standard reflectance attachment. Regular changes with time, both in the total absorbance (log base 10 of the reciprocal reflectance) and in the wave-length of the absorbance maxima (Figs. 1 and 2), were observed. Throughout, the gross form of the spectra remained characteristically

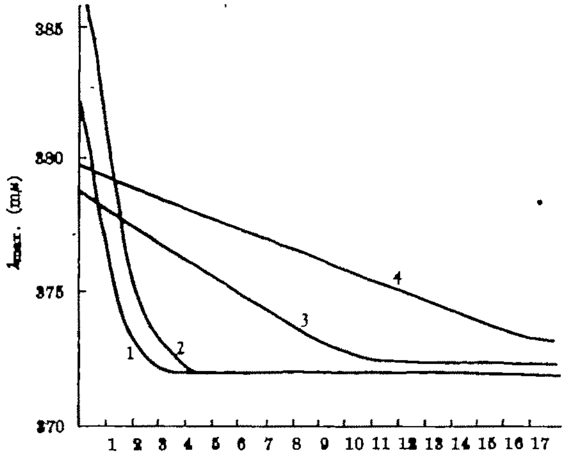

Fig. 2. Changes with time in the wave-length of the absorbance maxima of various mixtures of Michler's ketone and chromatographic alumina as measured by reflectance. 1, 2 mgm. ketone and 3 gm. acidic alumina; 2, 1 mgm. ketone and 3 gm. acidic alumina; 3, 2 mgm. ketone and 3 gm. basic alumina, 4, 1 mgm. ketone and 3 mgm. basic alumina

that of the ketone. The displacement of the absorbance maxima should be related to distortions in the electronic energy-levels of the ketone molecules due to interactions with the alumina on adsorption. The changes in absorbance at the wave-length of the maxima for the adsorbed species should be an index of the relative amount of the adsorbed species present at a given time. Further, the rates at which adsorption takes place on the different grades of alumina provide a measure of the relative activities of such adsorbents. When the solid–solid adsorption processes were essentially complete, the absorbance maxima were virtually identical with those of the ketone adsorbed on the same types of alumina from solutions. This confirms the visual impression as to the similarity of at least the end-result of these two processes. The adsorption from solution, of course, occurs far too rapidly to be studied kinetically, while the solid–solid process proceeds at a vastly retarded but measurable rate. It is hoped that the data being accumulated by reflectance will contribute to the knowledge of solid adsorptions and perhaps submit to a kinetic analysis which could help suggest the mechanism involved. A detailed account of this work will be published separately.

The financial support received from a Frederick Gardner Cottrell grant of the Research Corporation of New York is gratefully acknowledged.

Hydrocracking of Neopentane and Neohexane over Evaporated Metal Films

FOR the cracking of ethane in the presence of hydrogen over iron[1] and over nickel[2], it has been supposed that the molecule is adsorbed at adjacent carbon atoms (1–2 diadsorbed) prior to cracking. However, since work in this laboratory on the hydrocracking of higher hydrocarbons has given results which cannot readily be explained by 1–2 diadsorbed intermediates, the behaviour of neopentane and neohexane was investigated in order to establish the possibility of alternative mechanisms. In the case of the former, 1–2 diadsorption is impossible while in the latter it must be limited to the ethyl group attached to the quaternary carbon atom.

Table 1 shows results of reactions over evaporated films of nickel, tungsten, platinum and rhodium, using initial pressures of hydrogen of 45 mm. mercury and of hydrocarbon 3·7 mm. mercury. The metal films were prepared from spectroscopically standardized metals. Analyses were made after 5–25 per cent of the hydrocarbon had reacted, using liquid-modified gas adsorption chromatography[3]. The column, 60 ft. in length, with a squalane-on-'Pelletex' (a pelleted carbon black) packing, operating at 35° C., was capable of separating all saturated hydrocarbons from C_1 to C_6. The limit of detection was about 10^{-8} mole, equivalent to a pressure of 3×10^{-3} mm. mercury in the reaction vessel.

The results in Table 1 show that hydrocracking of neopentane and of propane occurred over nickel, tungsten and platinum with comparable ease, whereas neohexane reacted at temperatures up to 50 deg. C. below those for neopentane. Over nickel, hydrocracking of ethane required a temperature about 40 deg. C. above that for propane, and the overall activation energies for hydrocracking are 35 ± 5 kcal. mole^{-1} for both neopentane and propane and 69 kcal. mole^{-1} for ethane. These values may be compared with 34 and 54 kcal. mole^{-1} for propane[4] and ethane[2] respectively, obtained on nickel–kieselguhr catalysts using rather lower hydrogen-to-hydrocarbon ratios and lower temperatures. The order of catalyst reactivity for hydrocracking at the quaternary carbon atom is rhodium > tungsten > nickel > platinum, the same order as for propane. This order is quite different from that for the breaking of the C—N bond in methylamine and ethylamine, which is rhodium ≃ platinum > nickel > tungsten[5]. The reaction of neopentane on platinum is remarkable since the presence of 17 per cent *n*-butane in the product indicates substantial isomerization as well as cracking.

In the reactions of neohexane, cracking at the quaternary carbon atom to give isobutane and ethane as primary products predominated strongly on platinum and decreased in importance in the order platinum > tungsten ≫ nickel > rhodium, so that for rhodium the dominant initial cracking mode was in the ethyl group to yield methane and neopentane.

Table 1

Catalyst	Hydrocarbon	Temp. (° C)	Rate (mm. per hr. per 10 mgm. of catalyst)	Extent of reaction (per cent)	Distribution of product (per cent)*						
					M	*E*	*P*	*iso-B*	*n-B*	*neo-P*	*iso-P*
Nickel	Neopentane	230	0·3	8	95	4	1				
	Neohexane	188	0·4	10	46	9	5	13		27	
	Ethane	272	0·2	8	100						
	Propane	230	0·7	10	89	11					
Tungsten	Neopentane	202	0·07	2	57	17	11	15			
	Neohexane	161	0·2	7	33	19	6	36		6	
	Propane	188	0·7	25	65	35

Platinum	Neopentane	296	0·4	11	25	14	17	27	17		
	Neohexane	285	0·4	10	5	41	5	44		5	
	Propane	295	0·5	10	40	60					

* *M*, methane; *E*, ethane; *P*, propane; *iso-B*, isobutane; *n-B*, *n*-butane; *neo-P*, neopentane; *iso-P*, isopentane.

These results show that the claim of Haensel and Ipatieff[6] that, over a nickel/kieselguhr catalyst, bonds to a quaternary carbon atom are least susceptible to attack, is not of general validity for other catalysts. Furthermore, in the hydrogenation of 1–1 dimethyl-*cyclo*propane on nickel–kieselguhr at 150° C. (ref. 7), the sole product, *iso*pentane, indicates exclusive rupture of a bond to the quaternary carbon atom. In this case, however, the highly strained *cyclo*propane ring may invalidate direct comparison with the saturated hydrocarbons.

Although these results show that hydrocracking of a C—C bond can occur without 1–2 diadsorption, it does not follow that the adsorbed intermediate is attached to the catalyst at only one carbon atom. There is evidence for 1–3 diadsorption of neopentane in catalytic exchange with deuterium[8]. In the diadsorbed intermediates responsible for multiple exchange between deuterium and saturated hydrocarbons (cf. Anderson[9]), each carbon atom is normally linked to the surface by a single bond, and the 1–2 diadsorbed intermediate previously postulated for the cracking of ethane[1,3] is identical with that established for multiple exchange in ethane[10]. However, assuming a value of ΔH for adsorption by a single bond of -12 kcal. mole^{-1}, and using corresponding characteristic temperatures for exchange[8] and cracking, it follows that the average life-time of such a diadsorbed species will, at cracking temperatures, be only 10^{-3} to 10^{-4} of the life-time under exchange conditions. Furthermore, it is known that over both nickel and tungsten an increase in temperature favours the further loss of hydrogen atoms from the adsorbed hydrocarbon residue[11]: the reduced rate of exchange of neopentane[8] and ethane[10] over nickel at higher temperatures is probably due to the formation of strongly adsorbed species, multiply bonded to the surface. It seems unlikely, therefore, that the same diadsorbed species is the principal intermediate in both exchange and hydrocracking. We suggest, at least in hydrocracking reactions where 1–2 diadsorption is sterically impossible, that reaction proceeds via 1–3 diadsorbed species and that, in general, diadsorbed intermediates in hydrocracking reactions are comparatively strongly adsorbed on the catalyst surface by the loss of more than one hydrogen atom on at least one carbon atom.

We are grateful to the Shell Co. (Australia), Ltd., for a grant towards the cost of materials.

BIOCHEMISTRY

Assay of Corticosteroids in the Chick Embryo

FOR some time we have been studying various manifestations of the reaction induced in chick embryos by the inoculation of leucocytes from normal fowls (the Simonsen phenomenon) with special interest in the production of macroscopic foci on the chorioallantois[1]. In the course of this work it was observed that if hydrocortisone was added to the inoculum the number of foci was diminished and the embryo showed obviously retarded development.

Several studies of the effect of cortisone on the developing chick embryo have been reported[2–4]. They showed a moderate inhibition of growth with doses of the order of 0·3–0·5 mgm. per embryo. We have not found any reports of such studies with the newer types of anti-inflammatory corticosteroids.

Through the co-operation of Dr. T. F. McCrae of Glaxo Laboratories we have been able to test the following: cortisone alcohol, hydrocortisone alcohol, prednisone alcohol, prednisolone disodium phosphate and dexamethazone. All were used as suspensions in normal saline with the exception of prednisolone disodium phosphate which is freely soluble in water. In order to prevent any damage to the area used for inoculation of leucocytes, the suspensions were inoculated in 0·1 ml. vol. into the air space of twelve-day embryos and the eggs held vertically in the incubator for 1–2 hr. before being inoculated on the dropped chorioallantois with 2–5 × 10^6 fowl leucocytes in a volume of 0·1 ml. After four days further incubation at 38° C. the embryos were removed and weighed and the foci on the chorioallantoic membranes counted.

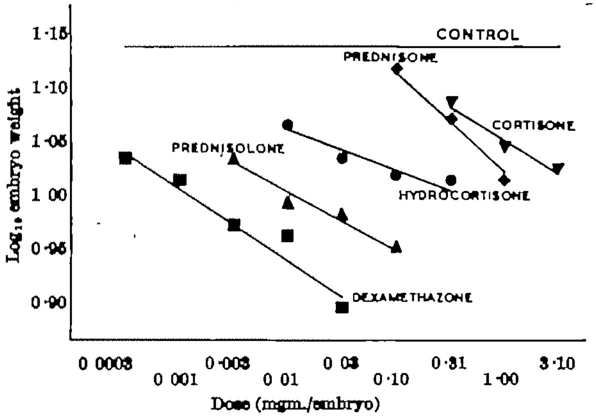

Fig. 1. Action of corticosteroids on embryo weights. Doses are shown in mgm./embryo, logarithmic intervals being used. The values have been adjusted to a uniform control weight of 13·8 gm.

The results for the significant range of doses of the five compounds used are shown in Fig. 1. Each point is the mean of a group of 8–16 embryos except for the highest doses of prednisolone and dexamethazone where some embryos died before the fourth day. The survivors from the larger doses of the 11-hydroxysteroids usually showed, in addition to retarded growth, definite pathological changes in the form of oedema, liver damage and abnormalities of feather growth. This was not seen with prednisone, where the effect seemed to be a simple retardation of growth.

The effect on focal counts from a standard inoculum of adult fowl leucocytes followed a similar trend. In

Table 1. ACTION OF CORTICOSTEROIDS IN REDUCING FOCAL COUNT ON CHORIOALLANTOIC MEMBRANE

Dose mgm. embryo	Prednisone per cent	Prednisone P	Hydro-cortisone per cent	Hydro-cortisone P	Pred-nisolone per cent	Pred-nisolone P	Dexa-methazone per cent	Dexa-methazone P
0·0003	—		—		—		40	0·02
0·001	—		—		—		10	<0·01
0·003	—		—		90	0·35	7	<0·01
0·01	—		35	0·05	30	0·01	5	<0·01
0·03	70	0·10	30	0·02	5	<0·01	0	<0·01
0·10	50	0·01	20	<0·01	2	<0·01	—	
0·31	50	0·01	5	<0·01	—		—	
1·00	30	<0·01	—		—		—	

All values are based on the median of the focal counts and indicate percentage of the corresponding control counts.

all experiments on randomly bred embryos there is a wide range of counts and the median has been taken as the most useful index of comparison. In Table 1 the medians have been adjusted as percentages of the corresponding control values and the statistical significance of their difference from the control shown by the value p as calculated from Student's test. When cortisone or prednisone was given by the air space no effect on focal count was observed and the values shown are from an experiment in which prednisone was mixed with the leucocytes just prior to their inoculation.

It will be seen that by both criteria the activities of the corticosteroids are in the same order:

$$\text{dexamethazone} > \text{prednisolone} > \text{hydrocortisone} > \text{prednisone, cortisone}$$

The striking difference between prednisone and prednisolone, which by the conventional tests in laboratory mammals are of approximately equal activity, is noteworthy and may reflect the absence of some enzymic capacity in the embryos.

These experiments are being extended to other corticosteroids, and exploratory work on the nature of the action of prednisolone on the focal count is in progress.

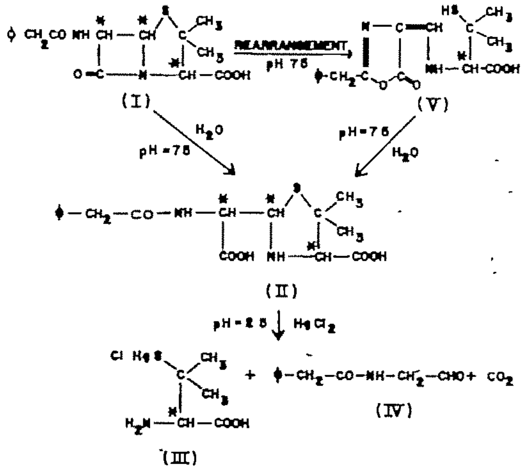
Degradation of Benzylpenicillin at pH 7·5 to D-Benzylpenicilloic Acid

IN acid aqueous solution, benzylpenicillin (I) becomes rearranged to D-benzylpenicillic acid[1a], and in alkaline aqueous solution, it is hydrolysed to the α-diastereomer of D-benzylpenicilloic acid[1b] (II). The product of degradation of benzylpenicillin in aqueous solution at pH 7·5 has not been identified. During work on the mechanism of antigenicity of penicillin, it was necessary to investigate the degradation pathway of benzylpenicillin under physiological conditions. It was found that in aqueous solution at pH 7·5, benzylpenicillin is degraded to D-benzylpenicilloic acid, which appeared to be present as a mixture of its diastereomers.



A solution of 714 mgm. (2·0 millimols) of sodium benzylpenicillin in 100 ml. of 0·2 M phosphate buffer was kept at 37° C. for 120 hr. During this time, the optical rotation fell from $\alpha(D,29) = +4\cdot1°$ for the fresh penicillin solution to $\alpha(D,29) = +0\cdot85°$. (Optical rotations were measured in a Schmidt and Haensch polarimeter with a 2-decimetre cell.) Ultra-violet spectrophotometry showed only the formation of an absorption peak at λ322 mμ and a decrease in ultra-violet end absorption. The peak at λ322 mμ has been demonstrated to be due to the formation of a very small quantity of D-benzylpenicillenic acid (V) by re-arrangement of benzylpenicillin[2a]. The decrease in optical rotation and in ultra-violet end absorption is consistent with the formation of D-benzylpenicilloic acid[1c,2b]. Also consistent with the formation of D-benzylpenicilloic acid is the observation that degradation of benzylpenicillin aqueous solution at pH 7·5 caused the liberation of a new acid group. This was indicated by the fact that additions of alkali throughout the course of the degradation were necessary in order to maintain the pH at 7·5.

Treatment of the reaction solution with one molar equivalent of mercuric chloride at pH 2·5 caused the immediate precipitation of the mercuric mercaptide of D-penicillamine (III) and the liberation of a Schiff aldehyde-positive compound into the supernatant liquid. This aldehyde was isolated as its 2,4-dinitrophenylhydrazone derivative by Shriner and Fuson's method[3]; yield, 500 mgm. (70 per cent). After crystallization from 95 per cent ethanol, the yellow needles melted at 193–194° C. (dec.); the reported melting point for benzylpenilloaldehyde 2,4-dinitrophenylhydrazone is 194–195° C. (dec.)[2c]. A mixed melting point of this compound with synthetic benzylpenilloaldehyde 2,4-dinitrophenylhydrazone was 193–195° (dec.). (Benzylpenilloaldehyde was prepared by synthesis[2d] and converted to its 2,4-dinitrophenylhydrazone by Shriner and Fuson's method[3]; after crystallization from 95 per cent ethanol, the yellow needles melted at 194–195° C. (dec.).) These melting-point data indicate that the phenylhydrazone derivative isolated was indeed benzylpenilloaldehyde 2,4-dinitrophenylhydrazone.

Mercuric chloride in aqueous acid solution immediately degrades D-benzylpenicilloic acid to the mercuric mercaptide of D-penicillamine (III), benzylpenilloaldehyde (IV), and carbon dioxide[1d]. The isolation, by this means, of benzylpenilloaldehyde in 70 per cent yield indicates that benzylpenicillin was hydrolysed to D-benzylpenicilloic acid.

The hydrolysis of sodium benzylpenicillin in *p*H 7·5 buffer yielded a monosodium benzylpenicilloate solution with a considerably less positive optical rotation (α(*D*,29) = + 0·85°) than that of a freshly prepared equimolar buffer solution (*p*H 7·5) of monosodium D-α-benzylpenicilloate (α(*D*,29) = + 1·98°). (Monosodium D-α-benzylpenicilloate was prepared by alkaline hydrolysis of sodium benzylpenicillin[1a], and recrystallized twice from water–acetone; melting point, 154–155° C. (dec.).) On standing at 37° C., the α-diastereomer underwent mutarotation; the optical rotation of this D-α-benzylpenicilloate solution fell to α(*D*,29) = + 0·44° after 60 hr. These observations suggest that the D-benzylpenicilloic acid formed by hydrolysis at *p*H 7·5 of benzylpenicillin may be present as a mixture of its diastereomers[1e].

The hydrolysis of benzylpenicillin at *p*H 7·5 may proceed through two possible pathways: (1) the α-diastereomer of D-benzylpenicilloic acid may be formed primarily by direct hydrolysis of the β-lactam linkage of benzylpenicillin, followed by epimerization to yield a mixture of its diastereomers; (2) benzylpenicillin may become degraded by slow rearrangement to D-benzylpenicillenic acid (V), which is rapidly hydrolysed to yield a mixture of diastereomers of D-benzylpenicilloic acid directly. In support of the latter pathway are the following observations: a small quantity of D-benzylpenicillenic acid was detected in the degrading benzylpenicillin buffer solution (see above). In aqueous solution at *p*H 7·5 at 37° C., D-benzylpenicillenic acid is hydrolysed rapidly to D-benzylpenicilloic acid ($t_{1/2}$ = 6·5 min.) (unpublished work). It must be noted that the degradation at *p*H 7·5 of benzylpenicillin may proceed through both these pathways simultaneously. Further work on this problem is in progress.

I thank Drs. E. Perlman, S. S. Schneierson, and H. Sobotka of the Mount Sinai Hospital for their interest during the course of this work, and the Charles Pfizer Laboratories, Brooklyn, New York, for a generous supply of sodium benzylpenicillin.

Formation of D-Penicillamine-Cysteine Mixed Disulphide by Reaction of D-Benzylpenicilloic Acid with Cystine

As part of a study of skin sensitization to benzylpenicillin, I have investigated the behaviour of D-benzylpenicilloic acid (4-carboxy-5,5′-dimethyl-α-phenylacetamido-2-thiazolidine acetic acid). This compound was found to give allergic cross-reactions of the contact dermatitis type with both benzylpenicillin and D-penicillamine (unpublished work). The allergic activity of D-penicillamine is probable due to its ability to react with cystine disulphide linkages of epidermal proteins to form D-penicillamine cysteine mixed disulphide residues[1]; the allergic cross-reactions between D-benzylpenicilloic acid and D-penicillamine might be due to the ability of the former to react also with disulphide linkages of epidermal proteins to form D-penicillamine-cysteine residues. There are no reports in the literature on the reactivity of D-benzylpenicilloic acid with either thiols or disulphides; I report here the reaction between D-benzylpenicilloic acid and cystine in aqueous solution at *p*H 7·5.

Cystine (96 mgm.) was suspended in 0·1 *M* aqueous solution of monosodium D-α-benzylpenicilloate at *p*H 7·5. (Monosodium D-α-benzylpenicilloate was prepared by alkaline hydrolysis of benzylpenicillin[2] and recrystallized twice from water–acetone; melting point, 154–155° C. (dec.). The material was found to be free of D-penicillamine by a paper chromatographic method capable of detecting less than 0·1 (unpublished work).) This reaction mixture was stirred at 37° C. for 24 hr. A 0·1 *M* aqueous solution of monosodium D-α-benzylpenicilloate under the same conditions served as a control. Aliquots of the reaction mixture supernatant and the control solution were analysed by descending paper chromatography with phenol–water as solvent. Monosodium D-α-benzylpenicilloate, D-penicillamine, cystine, and D-penicillamine-cysteine were chromatographed simultaneously to serve as standards. (D-Penicillamine-cysteine was prepared by the method of Tabachnick *et al.*[1], melting point, 195° C. (dec.).) The results are shown in Fig. 1. The reaction mixture supernatant contained another ninhydrin-positive compound with R_F identical with that of D-penicillamine-cysteine (R_F 0·33). This compound was eluted from the chromatogram. It gave a positive nitroprusside reaction only after reduction with alkaline cyanide solution, and yielded cysteic acid

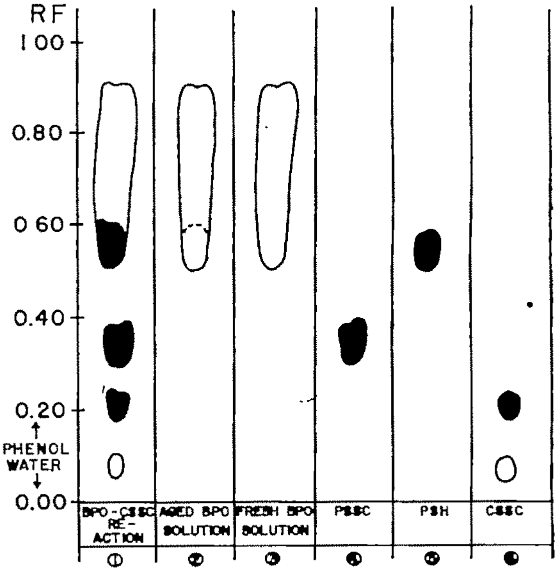

Fig. 1. Phenol–water paper chromatogram of: (1) the D-benzylpenicilloic acid (*BPO*)–cystine (*CSSC*) reaction solution; (2) the aged D-benzylpenicilloic acid (*BPO*) solution; (3) a freshly prepared D-benzylpenicilloic acid (*BPO*) solution; (4) D-penicillamine-cysteine (*PSSC*) standard; (5) D-penicillamine (*PSH*) standard; (6) cystine (*CSSC*) standard. Colour development was with ninhydrin

and penicillamine sulphonic acid after oxidation with aqueous bromine. These reactions have been described previously for D-penicillamine-cysteine[1]. These results indicate that D-penicillamine-cysteine mixed disulphide was formed by reaction of D-benzylpenicilloic acid with cystine.

The chromatogram of the reaction mixture supernatant also showed the presence of another spot superimposed on the D-benzylpenicilloic acid streak (Fig. 1). Its R_F was identical to that of D-penicillamine. Elution of this spot and oxidation with aqueous bromine yielded only penicillamine sulphonic acid. This spot appears to be due to the presence of D-penicillamine in the reaction mixture supernatant, probably formed by a secondary reaction between D-penicillamine-cysteine mixed disulphide and cysteine, the products of the D-benzylpenicilloic acid–cystine reaction. In aqueous solution at pH 7·5, D-penicillamine-cysteine was found to react with cysteine to yield D-penicillamine and cystine.

The formation of the mixed disulphide of D-penicillamine and glutathione was similarly observed when monosodium-D-α-benzylpenicilloate was treated with oxidized glutathione in aqueous solution at pH 7·5.

The mechanism of the D-benzylpenicilloic acid–cystine reaction is unknown. Early experiments suggest that the reactive form of D-benzylpenicilloic acid may be D-benzylpenamaldic acid (α-phenylacetamido - β - (α′ - amino - β′ - mercapto*iso*valeric acid) acrylic acid), traces of which appear to exist in tautometric equilibrium with D-benzylpenicilloic acid.

D-Benzylpenicilloic acid may react also with cystine disulphide linkages of epidermal proteins to form D-penicillamine-cysteine mixed disulphide residues. This chemical reaction might explain the allergic cross-reactivity between D-benzylpenicilloic acid and D-penicillamine; both of which may react with cystine disulphide linkages of epidermal proteins to form the D-penicillamine-cysteine antigenic-determinant group. Since benzylpenicillin is hydrolysed to D-benzylpenicilloic acid under physiological conditions[2], its allergic cross-reactivity with the latter and D-penicillamine (unpublished work) may be similarly explained.

I wish to thank Drs. E. Perlman, S. Schneierson and H. Sobotka of the Mount Sinai Hospital for their interest during the course of this work.

New Inhibitor of Monoamine Oxidase

THE following is the initial report of a structurally unique monoamine oxidase inhibitor, N-benzyl-N-methyl-2-propynylamine hydrochloride (*A*19120). This work includes *in vitro* action of this inhibitor on rat liver mitochondria as well as *in vivo* inhibition of monoamine oxidase of mouse brain and the liver.

The mitochondria were isolated from homogenate of rat liver by the differential centrifugation method of Hogeboom *et al.*[1], and suspended in $M/15$ phosphate buffer, pH 7·2. Homogenates of whole brain and liver tissue from test or control male mice were prepared by adding 1 ml. of the phosphate buffer for each 0·2 gm. tissue and homogenizing with Potter–Elvehjem homogenizers.

The monoamine oxidase activity of mitochondria or tissue homogenates was measured by a Warburg manometric technique at 37° C. The flasks contained tissue or mitochondria equivalent to 0·2 gm. of original tissue, $M/15$ phosphate buffer pH 7·2, and (in specified experiments) inhibitor. Serotonin creatinine sulphate was added at zero time to give a final concentration of $M/100$ in the 2·0-ml. reaction mixture. During the pre-incubation–equilibration period reaction mixtures were oxygenated for 5–10 min. Calculations were based on the uptake of oxygen during the first 60 min. of reaction-time.

The *in vitro* activity of N-benzyl-N-methyl-2-propynylamine hydrochloride was compared with that of several known compounds. All were pre-incubated for 25 min. The concentration of drug which produces 50 per cent inhibition of mitochondrial monoamine oxidase was read off the straight-line graph obtained by plotting the log concentration of inhibitor against per cent inhibition. The results were: *A*19120, 9×10^{-7} M; nialamide, 9×10^{-7} M; harmaline, 1×10^{-6} M; β-phenyl*iso*propyl hydrazine, 4×10^{-6} M; and iproniazid, 7×10^{-6} M.

Table 1. EFFECT OF PRE-INCUBATION TIME ON INHIBITION OF MONOAMINE OXIDASE *A*19120, HARMALINE AND IPRONIAZID

Inhibitor	Concentration $M/1$	Per cent inhibition after pre-incubation time* 0 min.	8 min.	15 min.	30 min.
*A*19120	5×10^{-7}	12	19	19	40
	1×10^{-6}	15	27	37	61
	2×10^{-6}	21	41	56	83
Iproniazid	$7·5 \times 10^{-6}$	4	12	25	76
Harmaline	5×10^{-7}	29	—	37	40

* Values as per cent of controls.

Table 1 summarizes the effect of increasing the pre-incubation time at 37° C. with *A*19120, iproniazid, and harmaline. Both *A*19120 and iproniazid show progressive inhibition with increasing pre-incubation time whereas harmaline does not.

In another series of experiments substrate was added to the mitochondria and the uptake of oxygen followed for 30 min., then the inhibitor was added from a second side-arm at a concentration which would have given 50 per cent inhibition of monoamine oxidase with 25 min. pre-incubation. Compound *A*19120 depressed the rate of oxygen consumption 22 per cent over controls, harmaline 54 per cent and iproniazid had no effect. This indicates that *A*19120 and iproniazid may not be identical in their mechanism of inhibition of monoamine oxidase.

Determinations for ammonia production by the Conway microdiffusion technique[2] and serotonin disappearance, by the method of Udenfriend *et al.*[3], were carried out on samples from Warburg vessels 60 min. after the addition of substrate to mitochondria. The ratios of oxygen/ammonia, oxygen/serotonin and ammonia/serotonin were 0·8–1·3 for controls, for *A*19120 at 1×10^{-6} M, and for iproniazid at $1·25 \times 10^{-6}$ M. This agreement between the theoretical ratio of 1·0 and experimental values indicates that these inhibitors probably act directly on the monoamine oxidase–serotonin system.

The reversibility of the inhibition effect was studied by a procedure similar to that of Udenfriend *et al.*[4]

Table 2. DURATION OF ACTION OF INHIBITION OF MONOAMINE OXIDASE IN MICE BY *A*19120 OR IPRONIAZID. DOSE, 200 MGM./KGM.

Days	Per cent inhibition			
	*A*19120		Iproniazid	
	Brain	Liver	Brain	Liver
1/6	68	73		
1	73	93	78	85
2	78	74		
3	74	65		
4	69	59		
5	59	49	58	37
6	55	44		
7	44	34		
8	50	38		
9	48	33		
10	17	6	30	12
12	17	0		
14	17	7	21	9

except that the activity of monoamine oxidase was measured by the Warburg technique. The inhibition produced by *A*19120 at 3×10^{-4} *M*, or iproniazid at 1×10^{-5} *M* (30 min. pre-incubation), was not reversed with four washings, whereas inhibition by 3×10^{-6} *M* harmaline was decreased from 84 to 50 per cent.

In a single experiment the duration of inhibition of monoamine oxidase of mouse brain and liver produced by one oral dose of 200 mgm./kgm. of *A*19120 or the same dose of iproniazid was determined. The results are in Table 2. Significant inhibition of brain monoamine oxidase occurred for at least seven days after administration of *A*19120. Although liver inhibition is less than that of brain after the first day, there is probably no preferential inhibition of the brain monoamine oxidase by *A*19120 at this pharmacologically high dose. Preliminary data from our laboratories also indicate that *A*19120 causes maximal increase in brain norepinephrine. Pharmacological work is now in progress and will be reported in a separate publication.

The results obtained in this work show that *A*19120 is a potent inhibitor of monoamine oxidase of a new structural type, and thus the present concepts of inhibition of monoamine oxidase should be enlarged.

Syntheses of Glucose, Cellobiose and Other Saccharides by *Acetobacter acetigenum* in a Lactate-buffered Glycerol Medium

WE have cultivated *Acetobacter acetigenum* N.C.I.B. 8132, a cellulose-forming micro-organism, in 10 litres of medium in 40 'Glaxo' flasks, which were shaken during incubation at 30° for twenty-one days. The medium contained (gm./l.): potassium dihydrogen phosphate, 2·0; crystalline magnesium sulphate, 1·0; crystalline ferrous sulphate, 0·01; ammonium hydrogen phosphate, 2·5; calcium D-pantothenate, 0·002; riboflavin, 0·002; biotin, 0·0001; glycerol, 30; lactic acid, 10·2; the *p*H value was adjusted with potassium hydroxide to 4·6. The metabolism solution was Seitz-filtered to remove cells and cellulose and concentrated to 500 ml. over barium carbonate, *in vacuo* at 35°. Activated charcoal, 'Ultrasorb *S.C.* 120/240' (British Carbo Norit Union) as used by Hughes and Whelan[1], was sieved through a British Standards 170 mesh and the material retained on the sieve was used to pack two 'Pyrex' glass columns (138 × 7·8 cm.) to a depth of 105 cm. In each column 1·9 kgm. of this charcoal rested on a pad of glass-wool overlayed with 100 gm. of 'Celite' added as a slurry in water. The columns were washed each with 5 litres of 50 per cent (v/v) aqueous ethanol and then each with 20 litres of distilled water. After removal of insoluble barium salts the metabolism concentrate was rediluted to 10 litres with distilled water and passed through the columns during 14 hr. Each column was eluted with 80 litres of distilled water followed by aqueous ethanol solutions (each of 50 litres) in which the respective ethanol percentages (v/v) were 0·5, 5, 10, 20, 35, and 50. Six aqueous ethanolic fractions, A_1–A_6, were collected and concentrated at 35°. Portions of each were de-ionized with 'Zeo-Karb 225' and 'Deacidite *E*' and chromatographed on paper against authentic sugars using (*a*) *n*-propanol/water/ethylacetate, 7:2:1 by volume; (*b*) pyridine/water/ethylacetate, 1:2:2 by volume; (*c*) ethyl acetate/acetic acid/water, 3:1:3 by volume. The chromatograms gave evidence of the presence of the following sugars: A_2, glucose, fructose, xylose, and ribulose; A_3, similar to A_2 together with a trace of cellobiose; A_4, mainly cellobiose; A_5, cellotriose and cellotetraose. Fraction A_2 was then de-ionized and submitted to column partition chromatography according to the procedure of Lemieux, Bishop and Pelletier[2], which involves the use of 'Celite No. 535' to hold the stationary phase. After irrigation with water-saturated *n*-butanol, the column was extruded and cut into zones as determined by an alkaline permanganate spray. A fraction was separated which, after several further passages through the 'Celite' and a final purification by band paper chromatography, yielded 45 mgm. of a substance which had the mobility of glucose when chromatographed in two different solvent systems. An acetate was prepared by heating with anhydrous sodium acetate and acetic anhydride, and after purification this had m.p. 131°, alone or mixed with authentic β-penta-acetyl glucose of m.p. 131°. The infra-red spectra of both acetates were compared and no significant differences could be observed. (Found: C, 49·3; H, 5·8 per cent. Calc. for $C_{16}H_{22}O_{11}$: C, 49·2; H, 5·7 per cent.)

The procedures by which glucose had been isolated were now applied to fraction A_4, yielding 52 mgm. of a substance which showed the mobility of cellobiose when run on paper chromatograms in different solvent systems. The substance was acetylated with pyridine and acetic anhydride and the purified derivative had m.p. 191°, unchanged by admixture with authentic β-cellobiose octa-acetate, m.p. 191°. (Found: C, 49·7; H, 5·7 per cent. Calc. for $C_{28}H_{38}O_{19}$: C, 49·6; H, 5·6 per cent.) The infra-red spectra of this octa-acetate and that of authentic β-cellobiose octa-acetate were without significant differences.

When lactate is metabolized by *A. acetigenum* in absence of other sources of carbon it is mainly oxidized through acetate to carbon dioxide, though in certain liquid media it can serve as a source for formation of cellulose[3]. It seems probable that in our experiments the lactate played a dual part, some of it suffering oxidation and thereby sparing glycerol for cellulose synthesis, and some of it undergoing conversion to a metabolite on the pathway to cellulose. So far as we are aware, neither glucose nor cellobiose has hitherto been isolated from among the products of bacterial action on either glycerol or lactate, although the formation of glucose in cultures of *Poria vaillantii* on a glycerol medium has been reported by Sison and Schubert[4], while Horecker[5] has suggested a cyclic mechanism by which this conversion may be effected.

It is proposed to report the work in further detail elsewhere.

Distribution of Protein-bound Aminoazo Dyes in the Rat Liver Microsome

EVIDENCE has been obtained that rat liver microsomes are the site where the formation of protein-bound aminoazo dyes occurs[1–3]. On the other hand, one of the most important parts played by the microsome is known to be protein synthesis. Littlefield *et al.*[4] further fractionated the microsome by means of sodium deoxycholate and pointed out that the protein in the deoxycholate-insoluble fraction, ribonucleoprotein particles, showed a particularly high turn-over rate, suggesting that protein is in fact synthesized in this fraction. This suggestion was supported by other authors[5–7].

In investigating the carcinogenesis due to aminoazo dyes, it is an inevitable question whether the protein-bound dye is detectable even in the fraction with such a high turn-over rate as the microsome ribonucleoprotein fraction. Despite the fact that Arcos and Arcos[3] are inclined to the view that no protein-bound dye was found in this fraction, we repeated a similar experiment but on a somewhat larger scale, since their evidence seemed to be inconclusive.

Rats which were fed 3′-methyl-4-dimethylaminoazobenzene coated on rice (0·06 per cent) were killed after 2 weeks when the protein-bound dye is considered to be a maximum. The liver microsomes were prepared according to Schneider's method[8] and washed once with 0·25 *M* sucrose solution. The unsedimented fluid was designated as 'supernatant fraction'. The microsomes were further fractionated by means of sodium deoxycholate as proposed by Littlefield *et al.*[4]. Thus we obtained three fractions, namely, deoxycholate-insoluble fraction (ribonucleoprotein fraction) and deoxycholate-soluble fraction from microsomes and the supernatant fraction. A small portion of each fraction was withheld for the protein[9] and ribonucleic acid[4] assays and the rest was subjected to protein-bound dye (polar dye) determination[10,11].

The results are summarized in Table 1. This clearly shows that a definite amount of protein-bound dye is detected in the ribonucleoprotein fraction. The total amount of this protein-bound dye in the ribonucleoprotein fraction is obviously lower than that in the other fractions. If, however, the protein-bound dye concentration is expressed on a per unit mgm. protein basis, the figures for the three fractions stand very closely to each other.

Table 1. DISTRIBUTION OF POLAR DYE AMONG CELL FRACTION

	Fraction	Microsome deoxycholate -insoluble	Microsome deoxycholate -soluble	Supernatant
Exp. 1	Liver used (gm.)	87		
	Protein (mgm.)	105	750	
	Ribonucleic acid (mgm.)	63	3·0	
	Polar dye (γ)*	2·6	27	
	Polar dye (γ)/100 mgm. protein	2·5	3·6	
Exp. 2	Liver used (gm.)	60		
	Protein (mgm.)	65	530	2,700
	Ribonucleic acid (mgm.)	56	18	
	Polar dye (γ)*	2·0	15	93
	Polar dye (γ)/100 mgm. protein	3·1	2·8	3·4

* The amount of polar dye is expressed in terms of DAB tentatively.

The significance of the finding must await further experiments, which are now being carried out here.

This experiment was supported partly by the grant from the Ministry of Education, Japan.

Water-soluble, Non-fibrous Deoxyribonucleoprotein from Calf Thymus Nuclei

A WATER-SOLUBLE, non-viscous form of deoxyribonucleoprotein has been isolated from purified calf thymus nuclei by a process that minimizes enzyme degradation. Previously the only preparation of deoxyribonucleoprotein generally accepted as undegraded has been the fibrous one, forming gels in water and only slightly soluble, with a molecular weight of 17 million[1].

Fresh calf thymus glands are frozen immediately on removal from the animal and ground to a powder in the frozen state in the presence of 'dry ice'. Only this procedure has been found to produce intact, round nuclei, as confirmed by microscopic examination, without excessive clumping, when the ground material is suspended in the purification medium at 0–4° C.

The purification medium is modified from those of Dounce *et al.*[2] and Philpot and Stanier[3], and is composed of 0·44 *M* sucrose, 40 per cent glycerol, 0·039 *M* sodium glycerophosphate, 0·019 *M* citrate buffer (*p*H 6·1, ionic strength 0·15).

Table 1. MOLECULAR WEIGHTS AND PARAMETERS FOR AVERAGE-SIZED PARTICLES OF FIBROUS AND NON-FIBROUS DEOXYRIBONUCLEOPROTEIN

Prep.	Solvent	ν_e (c.c./c.c.)†	a/b	Av. $S(20w) \times 10^{13}$	$M \times 10^{-6}$
A. Fibrous*	1 *M* NaCl-PO$_4$	4,030 ± 770	291 ± 31‡	43 ± 1·5§	15·9 ± 2·4
B. Non-fibrous, stored at 4°	1 *M* NaCl-PO$_4$	1,002	135	8·2	0·75
Non-fibrous, lyophilized	1 *M* NaCl-PO$_4$	674	108	9·5	0·79
Same	0·7 m*M* PO$_4$	591	96	7·3	0·49

* This preparation, entirely corresponding, was made and studied at Pollards Wood Research Station, Chalfont St. Giles, Bucks., England.

† This viscosity increment was obtained from the intrinsic viscosity at zero gradient, assuming a partial specific volume of 0·658 (ref. 8).

‡ Limits of error calculated to take into account the effect on viscosity of the known heterogeneity of the material.

§ The error is the standard deviation for the scattering of points from the straight line calculated by least mean squares obtained for the line portion of a typical sedimentation coefficient curve.

The intact nuclei are rapidly washed with this medium and centrifuged at 1,200*g*. The process is repeated four times, followed by a slow-speed centrifugation to remove whole cells and clumps. Immediately afterwards, the nuclei are extracted with water and centrifuged three times at 4° C. This washing with water appears to be of special significance for the chemical interactions determining the state of the deoxyribonucleoprotein, and will be the subject of a forthcoming publication. The swollen gel of nuclei is adjusted to 0·14 *M* sodium chloride and hand-homogenized mildly but rapidly, the process taking only about a minute. A finely divided mass of disrupted nuclei is thus obtained, giving a solution of non-fibrous deoxyribonucleoprotein after dialysis against 0·7 m*M* phosphate at *p*H 9, at 4° C. and, finally, clarification at 25,000*g*. The resulting solution was used for the viscosity and sedimentation work reported here.

It should be pointed out that fibrous deoxyribonucleoprotein is obtained from the nuclei washed in the medium, if, instead of the washing with water and hand homogenization in 0·14 *M* sodium chloride, the purified nuclei are dissolved directly in 1 *M* sodium chloride and clarified by centrifugation. The fibrous deoxyribonucleoprotein thus obtained and described here corresponds to preparations previously reported in the literature[1,4].

Viscosities were measured in 4-bulbed Ubbelohde viscometers, in those of the Frampton type[5], and in a Couette viscometer, to give a range of velocity gradients of 1–600 sec.$^{-1}$.

The distribution of sedimentation coefficients corrected to 20° C. in water was determined in the Spinco Model *E* analytical ultracentrifuge and calculated by the method of Shooter and Butler[6]. The solvent used was 1 *M* sodium chloride, 0·7 m*M* phosphate, *p*H 7·1 and 0·7 m*M* phosphate for the non-fibrous deoxyribonucleoprotein only. Ultraviolet absorption optics permitted measurements at concentrations as low as 0·01 per cent (optical density equal to 1) or less.

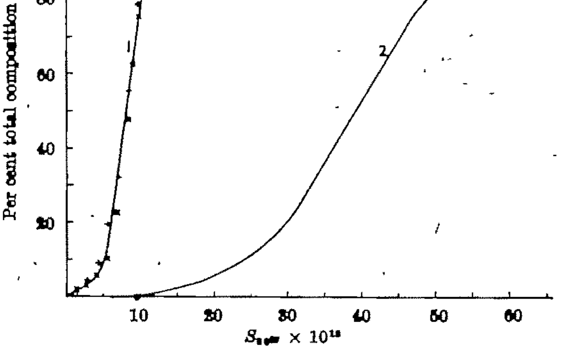

Fig. 1. Curves for distribution of sedimentation coefficients, corrected to water at 20° C., for non-fibrous and fibrous deoxyribonucleoprotein in 1 *M* sodium chlorate, 0·7 m*M* phosphate. Curve 1: Non-fibrous deoxyribonucleoprotein at a concentration of 0·091 mgm./c.c. Pluses—at 11·95 minutes after the extrapolated zero time (6); crosses—at 23·95 minutes after zero time. Curve 2: Fibrous deoxyribonucleoprotein from unextracted nuclei at 0·037 mgm./c.c. (courtesy of Dr. K. V. Shooter)

Concentrations were determined by nitrogen analysis and dry weight (indicating 17 per cent nitrogen in deoxyribonucleoprotein), or by the ultraviolet absorption at 260 mμ for preparations for which the extinction coefficients were known.

Viscosity and sedimentation determinations for both non-fibrous and fibrous deoxyribonucleoprotein, summarized in Table 1, show the striking contrast between these two forms. Fig. 1 shows that not only is the average sedimentation constant of the non-fibrous deoxyribonucleoprotein much lower than that of the fibrous, but also that it is distinctly more homogeneous; thus there is an increase in proportionate slope and also the last 5 per cent of highly aggregated material is eliminated for the non-fibrous sample. Whereas the fibrous deoxyribonucleoprotein shows an average sedimentation constant of 39 *S* at a concentration of 0·037 mgm./c.c. in molar salt, that observed for the non-fibrous preparation is strikingly lower, namely, 8·2 *S*. Paralleling this contrast is that observed for the axial ratio *a*/*b* for the fibrous form being 291 and that for the non-fibrous form 135 in molar salt or 96 in dilute buffer. Molecular weight calculations from these data lead to the values of 16 million for fibrous deoxyribonucleoprotein and 0·77 million for the non-fibrous form in molar salt for the average-sized particles, assuming effective hydrodynamic ellipsoids[7].

All the results clearly support the hypothesis that there are much smaller sub-unit particles of deoxyribonucleoprotein than those of fibrous deoxyribonucleoprotein, commonly accepted as such. Enzymatic degradation during the preparative steps is most unlikely; first, because the mild hand homogenization, the all-important step connecting fibrous preparations with the non-fibrous ones, is accomplished so rapidly, and secondly, because in a control experiment, nuclei washed with the purification medium only yielded fibrous deoxyribonucleoprotein after standing at 4° for as long as 4 days in 0·14 *M* sodium chloride.

Work now in progress indicates that the deoxyribonucleic acid obtained from the non-fibrous deoxyribonucleoprotein by salt and detergent dissociation has an average sedimentation coefficient of 5·3 *S* in molar salt, which is lower, as expected, than for the corresponding deoxyribonucleoprotein preparation. This finding lends further support to the view that the non-fibrous preparations are comprised of particles which are sub-units of the conventional fibrous particles.

This work was supported in part by a grant, No. *A* 2401, of the National Institutes of Health. I thank Prof. J. A. V. Butler for his hospitality, and Dr. K. V. Shooter for his collaboration and helpful advice.

PHYSIOLOGY

Adenosine Triphosphate and Maintenance of Shape of the Human Red Cells

ALTHOUGH the mechanism with which red blood cells maintain their biconcave shape has been studied by a number of investigators, it has not yet been clarified. Some twenty years ago Furchgott and Ponder[1] proposed the existence of an antisphering factor in the blood plasma, but later Ponder[2] himself cast doubt on this. More recently, Prankerd[3] suggested that the red cell envelope might possess certain contractile properties dependent upon a continuous regeneration of adenosine triphosphate, according to the evidence that incorporation of phosphorus-32 is low in the esters of the stroma obtained from those species with spheroidal red cells or from patients with hereditary spherocytosis. However, no detailed experiment on the shape of the cells has been reported by Prankerd or by others.

In our experiment human red cells obtained by venipuncture were washed three times with physiological saline, and a 7 per cent suspension of these cells in physiological saline was incubated at 37° C. with a final concentration of 2×10^{-2} *M* sodium fluoride. During the incubation the discoidal shape of the cells changed to a crenate one at first, and after 6 hr. almost all the cells were transformed to smooth spheres. At this time the cells were washed with cold physiological saline four times in order to wash out the fluoride thoroughly and incubated further with 5×10^{-3} *M* glucose, 1×10^{-2} *M* inosine, and 2×10^{-3} *M* adenine sulphate to restore the content of adenosine triphosphate of the cells as in the previous experiments[4]. After 2 hr. the shape of the incubated cells turned to a biconcave disk or a shallow cup-form again. The disk–sphere transformation and vice versa could be repeated several times, and the phenomenon was also observed in red cells obtained from fresh or long-preserved human blood or from rat or pig blood as well.

In parallel with the morphological observation described above, the adenosine triphosphate in the cells was estimated as acid-soluble total phosphate adsorbed on and eluted from 'Norit *A*', by Fiske and Subbarow's[5] method, or the sum of adenosine triphosphate and adenosine diphosphate content was calculated from optical density at 260 mμ after separation by means of a slightly modified Cohn and Carter's ion exchange chromatography[6]. The results shown in Table 1 indicate that more than two-thirds of the original values of nucleotides was necessary for the maintenance of discoid shape, and that the cells change to smooth spheres as the level of nucleotides decreases to one-fourth or one-fifth of the original level. As it is well established that most of the nucleotides in the blood cells belong to adenosine phosphates, especially to adenosine triphosphate[7], the amount of nucleotide phosphates estimated as above approximately equals the amount of adenosine triphosphate.

The same transformation was also observed during the preservation of blood in ACD medium at 4° C.: the biconcave disk shape changed to crenated disk at

Adenosine triphosphate and adenosine diphosphate μM/100 ml. cells	98	70	34	5 1	—

first (after about two weeks), and then to crenated spheres and finally to smooth spheres (after more than about five weeks). Calculating from the results which were obtained by the gradient elution technique of ion-exchange column chromatography on 'Dowex 1' (formate system)[8], the adenosine triphosphate content of the cells is summed up again in Table 2 together with morphological observations. M. Nakao *et al.*[4] have reported recently that human red cells, which were spherical after storage for several weeks at 4° C. in ACD solution, transformed to a shallow bowl form after incubation with added adenine and inosine, being accompanied by a marked rise of adenosine triphosphate content in the cells.

According to earlier work[9], round ghost cells obtained from long-stored red cells changed to a goblet-like shape with the addition of 0·003–0·04 *M* or higher concentration of adenosine triphosphate (optimal *p*H 8), and they returned to the former shape upon addition of ethylenediamine tetraacetate in 0·004 *M* concentration shortly after the addition of adenosine triphosphate.

The observations presented here lead us to the following conclusions:

(1) The presence of blood plasma is not necessary for the red cells to maintain their discoidal shape.

(2) The disk–sphere transformation of red cells and vice versa can take place without any change in hydrogen ion and cation concentration and ionic strength in the medium.

(3) If adenosine triphosphate or adenine nucleotide content in red cells is greater than a certain level, the normal shape of the cells is maintained, and if it is below this level, the shape becomes crenate, and when it decreases further, below another lower level, the shape of the cells changes to a perfect sphere.

It remains obscure, however, whether the maintenance of the shape of red cells depends solely on the level of adenosine triphosphate or on the turn-over of adenosine triphosphate.

An experiment aimed at extracting actomyosin-like protein from red cell ghosts is now in progress.

An Abnormal Serum Protein in Experimental Poisoning by Cadmium and other Metals

IT has been shown by Friberg[1] that men exposed for many years to the hazard of cadmium inhalation can excrete a protein having a low molecular weight in their urine. In order to investigate this phenomenon further, an investigation has been carried out on the changes in serum protein produced in the albino rat, following the administration of cadmium salts, using the starch-gel electrophoresis method of Smithies[2], together with the modification in the buffer system suggested by Poulik[3].

Among several other changes, it has been observed that following the intraperitoneal or subcutaneous injection of 1 mgm. per kgm. of cadmium as cadmium chloride, an abnormal protein appeared in the serum, which could be seen when the serum was analysed on

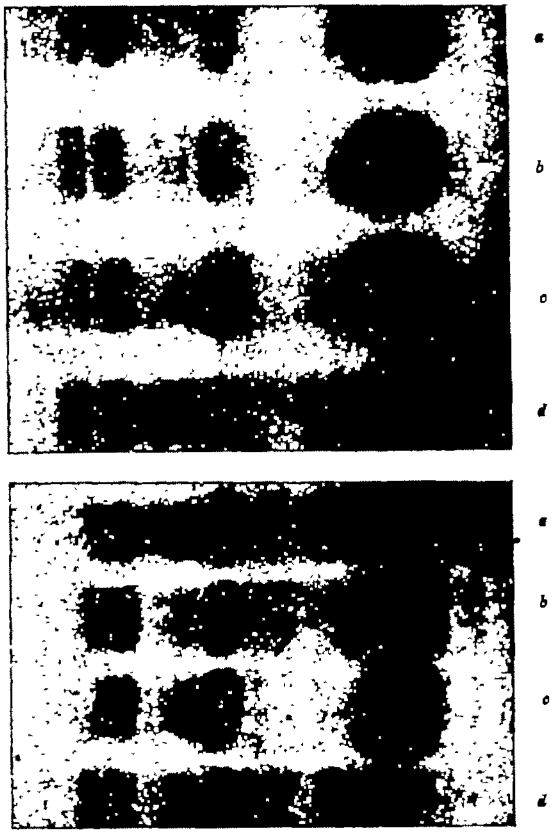

Fig. 1. Starch-gel electrophoresis of sera from albino rats, injected intraperitoneally with *a*, saline, *b*, cadmium, *c*, zinc and *d*, mercury, 1 mgm. per kgm. (as chloride) in each case. Top, continuous *tris*-citrate buffer system, 500 V., 10 m.amp., 2 V. cm.$^{-1}$ for 20 hr. Bottom, discontinuous borate, *tris*-citrate system, 500 V., 20 m.amp., 6 V. cm.$^{-1}$ for 4 hr.

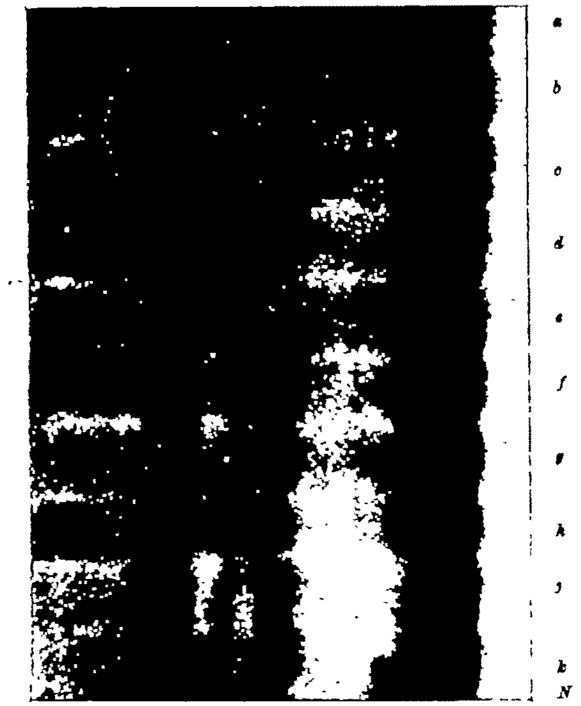

Fig. 2. Starch-gel electrophoresis of rat sera (continuous *tris*-citrate buffer system 500 V., 10 m amp., 2 V. cm.$^{-1}$ for 20 hr.) from rats injected with 1 mgm. per kgm. of the following metals. *a*, beryllium, *b*, cadmium, *c*, chromium, *d*, cobalt, *e*, copper, *f*, iron, *g*, lead, *h*, manganese, *j*, mercury, *k*, nickel, *N*, normal saline

a Connaught starch gel, as described by Smithies. Poulik described a discontinuous buffer system for use in starch-gel electrophoresis, and it has been found that an improved picture of this abnormal protein can be obtained by using the *tris*-citrate buffer, described by him, as a continuous buffer throughout the system.

The protein, following a single injection, usually appeared within 24 hr., and it slowly disappeared in about a week. Mercury was found to behave in a similar way, when administered in the same concentration, but zinc did not (Fig. 1). At a concentration of 20 mgm. per kgm., however, zinc gave rise to the abnormal protein.

This abnormal serum protein has been isolated from the serum of cadmium-poisoned rats as follows. Preliminary experiments had established that the protein was precipitated from serum by 37 per cent saturation by ammonium sulphate, and that it moved as an α-1-globulin when submitted to paper electrophoresis or to a cellulose electrophoretic column using phosphate borate buffer as described by Gedin and Porath[4]. Forty rats were given 1 mgm. per kgm. of cadmium chloride and after 24 hr. the blood was removed by cardiopuncture. After the blood had clotted, the serum was removed and saturated ammonium sulphate solution was added to give 40 per cent saturation. The mixture was left at 0° C. for 1 hr.; the precipitated protein was centrifuged off, dissolved in distilled water, dialysed free of ammonium sulphate, and finally freeze-dried. The resultant solid was dissolved in physiological rat saline, introduced into a Porath column 2 × 150 cm. and run for 48 hr., at 1,400 V. and a current of 24 m.amp., using the phosphate–borate buffer as described. The fractions from this column were dialysed and freeze-dried, and each fraction was analysed by starch-gel electrophoresis using the continuous *tris*-citrate buffer system. The appropriate fractions were combined, redissolved and freeze-dried. 0·6 gm. of the protein was isolated. As the cadmium chloride used in the experiment had been prepared from radioactive cadmium-115, radioactivity measurements showed that the protein did not bear any cadmium.

A group of other common metals, some generally considered toxic, and others present in trace amounts in the body, was administered, all at a dose-rate of 1 mgm. per kgm. body-weight. The response of the animals (so far as the production of the protein after 24 hr. was concerned) was in the following order: mercury > beryllium, cadmium, copper > manganese > chromium, nickel. Cobalt, lead and iron did not give a visible band under these conditions (Fig. 2).

The observation that mercury and cadmium salts produce the abnormal line, in the serum of rats, and can also give rise to proteinuria in man, when absorbed over many years, may help to clarify the mechanism of metal poisoning and proteinuria.

Experiments are in progress to locate the source of production of this protein using fluorescent antibody techniques, and also to elucidate possible auto-immune reactions to this protein in the rat, following our observation that the protein disappears from the blood after some 6–8 weeks of thrice-weekly doses of 0·5 mgm. per kgm. of cadmium, administered intraperitoneally.

A full account of this work will be published shortly.

Comparison between the Effects of Cysteine and of Anoxia on the Rate of Mitosis in Lens Epithelium

BOTH anoxia and pretreatment with certain thiols will reduce the sensitivity to radiation of many types of living organisms. The possibility that thiols protect against radiation damage because they lower oxygen tension has been reviewed by Gray[1] and by Pihl and Eldjarn[2]. In spite of all the work done it is not yet clear whether the protective thiols act by inducing tissue anoxia or by some other means.

Pirie and Lajtha[3] found that injection of cysteine into a rabbit inhibited cell division in the lens epithelium, the mitotic inhibition beginning about 18 hr. after injection and lasting four days. von Sallmann[4] had previously shown that cysteine given before irradiation will prevent radiation cataract in the rabbit lens. Since measurement of mitosis in lens epithelium is a simple quantitative method of assessing an effect of cysteine *in vivo*—whether related to protection against radiation or not—we thought it worth while to compare the mitotic inhibition caused by cysteine with that caused by lack of oxygen.

Rats, aged 7–11 weeks old, were used, and comparisons were made between normal and treated litter mates. Cysteine treatment consisted in a single intravenous injection of 10 per cent cysteine, at a dosage of 100 mgm. cysteine/100 gm. body-weight. The rats were killed at about 8, 18, 24, 32 and 48 hr. after injection. Anoxia was achieved by keeping the rats in an atmosphere of about 5 per cent oxygen, 1 per cent carbon dioxide and 94 per cent nitrogen for up to 18 hr. Rats were killed after 7, 9 and 18 hr. anoxia, and after 18 hr. anoxia followed by 2, 6 or 30 hr. in the normal air. Total mitotic counts were made in whole flat preparations of lens epithelia[5].

The duration of anoxia is definite, but the length of time during which cysteine, plus cystine and other breakdown products, were present in the blood and aqueous humour is not known, nor is the necessary effective concentration. von Sallmann, Dische, Ehrlich and Munoz[6], however, have shown that, in the rabbit given a somewhat smaller intravenous dose of cysteine (70 mgm./100 gm.), the cysteine plus cystine reached maximum levels in the blood and aqueous humour within 1–2 hr., and in 6 hr. had fallen to well below half these values. It is reasonable to assume, therefore, that the length of time during which cysteine and its products were present at effective levels was certainly no longer than the 18-hr. period of anoxia.

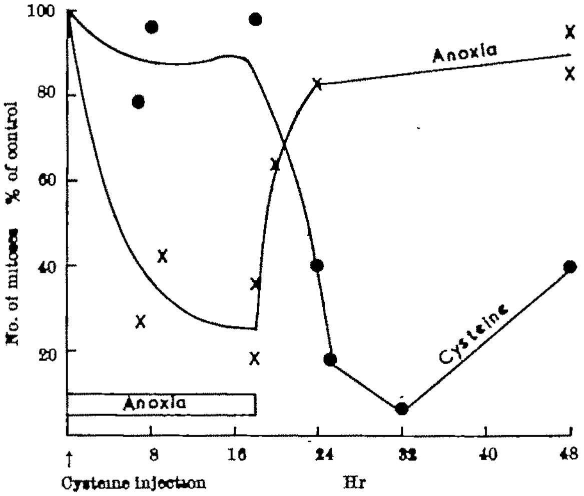

Fig. 1. Comparison between the effects of cysteine (●) and of anoxia (×) on the rate of mitosis in lens epithelium

The effect of cysteine, and of anoxia, on the number of mitoses in the lens epithelium is shown in Fig. 1. There were no damaged cells in any of the preparations. The figure shows that, after 7, 9 and 18 hr. of anoxia, the rate of mitosis had dropped to well below 50 per cent of normal; when the rats were returned to air there was a rapid return to the normal level, recovery being probably complete within 6 hr. With cysteine, on the other hand, there was no significant decrease in mitosis until 24 hr. after the injection, and the rate was still depressed at 48 hr.

Thus in this particular system, and under these particular conditions, the effect of cysteine can be clearly distinguished from that of anoxia.

Serotonin, a Melanocyte-stimulating Component in the Dorsal Skin Secretion of *Xenopus laevis*

IT is well known that a variety of substances are able to produce a dispersion or concentration of the pigment granules in the melanocytes of Amphibia *in vivo*. However, the number of compounds which produce a dispersion or concentration of these granules in melanocytes of isolated pieces of skin is much smaller. Any secondary reactions may be excluded by this latter *in vitro* method of testing. At the present stage of investigation, *in vitro* studies may be of value, though it should be realized that what happens in Nature may not be comparable.

In a series of investigations, using phenylalkylamines, Burgers[1] found a correlation between melanocyte activity *in vitro* and chemical structure. Furthermore, he described[2] a dispersion of the pigment granules of melanocytes in isolated webs of *Xenopus laevis* after administration of an extract of the dorsal skin secretion of the same species. The purpose of the present investigation was to determine the chemical nature of the active substance in this secretion.

After extraction of dried, defatted skin secretion with methanol, the presence of several indole derivatives could be demonstrated chromatographically, and one of these proved to be active in the *in vitro* test. Catecholamines could not be detected in the extracts. The ultra-violet absorption spectrum of the active indole compound showed a maximum at 275 mμ with a shoulder at 295 mμ, suggesting the presence of a hydroxy-group at position 5 (ref. 3).

The absorption maxima showed an acid-base shift, indicating a free hydroxy-group. This was confirmed by paper electrophoresis at *p*H 13 during which the indole component moved towards the anode. Adsorption of the active compound on 'Amberlite *HCG-50* (H$^+$)', migration to the cathode during paper electrophoresis at *p*H 7, and the fluorescence reaction of Shepherd *et al.*[4], suggested the presence of 5-hydroxytryptamine (serotonin) or its derivatives. Identity of the R_F-values of the active indole compound with

Table 1. R_F-VALUES OF THE ACTIVE INDOLE COMPOUND COMPARED WITH SYNTHETIC SEROTONIN

Developing liquid	Active indole compound	Synthetic serotonin
20 per cent aqueous potassium chloride	0·34	0·34
n-Butanol/hydrochloric acid (98 : 2), after impregnating in 0·5 *M* potassium chloride	0·41	0·43
n-Butanol/acetic acid/water (4 : 1 : 5)	0·49	0·49
iso-Butanol-1, saturated with water	0·19	0·22
Phenol/0·1 *N* hydrochloric acid (85 : 15)	0·49	0·48

synthetic serotonin in several chromatographic systems led us to the conclusion that the active compound is identical with serotonin.

Using the *in vitro* test, synthetic serotonin proved to be active. Activity of serotonin with respect to the melanocytes *in vivo* has been described by Davey[5], whereas Wright and Lerner[6] announced a concentrating effect of serotonin *in vitro* in *Rana pipiens*. The presence of serotonin in the venom of *Bufo marinus* has been ascertained by Udenfriend *et al.*[7], who stressed its role as a precursor of the well-known methylated derivatives bufotenine, bufotenidine, etc.

Whether there exists a correlation between the melanocyte activity *in vitro* and the chemical constitution of tryptamine derivatives is being investigated.

I am indebted to Prof. G. J. van Oordt for his interest and encouragement and to Miss A. W. van Wijngaarden, Mr. J. W. Huismans and Mr. A. D. F. Addink for their skilful assistance.

Sodium and Potassium in Mitochondrial Membrane Fractions

In a preliminary attempt to explain the observations that muscle[1] and liver[2] mitochondria are able to transport actively potassium but not sodium, the concentrations of these ions in mitochondrial membrane fractions were studied and compared with those in intact mitochondria. The results indicated that the specific activity (μgm. sodium or potassium/mgm. dry weight) of sodium was several times greater in mitochondrial membrane fractions than in intact particles, whereas the reverse was found with potassium.

Heart mitochondria were isolated from 6–9 lb. male rabbits as described previously[3], and rabbit liver and kidney mitochondria were prepared as described by Hogeboom[4]. Mitochondria were washed three times with the same fluid used in homogenizing the tissues and then suspended with 0·25 *M* sucrose. To 9 ml. of the mitochondrial suspension, 1 ml. of a 3 per cent solution of deoxycholic acid was added and the mixture rapidly stirred with a glass rod until it became clear. The deoxycholic acid solution was freshly prepared for each experiment by adding 15 ml. water to 750 mgm. deoxycholic acid (Mann Research Laboratories), and then solubilizing the acid by stirring in 1·4 gm. *tris* [*tris*(hydroxymethyl)aminomethane] buffer. The *p*H of the solution was adjusted to 7·6 by slowly adding 5 *N* hydrochloric acid and then diluting to 25 ml. with water. To mitochondria which were not disrupted, 1 ml. of either 0·25 *M* sucrose or 0·46 *M tris* buffer (*p*H 7·6) was added. The rest of the procedure was similar to that described[5] for isolating a membrane fraction from 0·44 *M* sucrose suspensions of rat liver mitochondria. The pellet obtained by centrifugation of the 25,000*g* supernatant for 1 hr. at 105,000*g* was called the membrane fraction. Dry-weight determinations and analyses of sodium and potassium were carried out as described previously[1].

Unless otherwise indicated, mitochondria were suspended with 0·25 *M* sucrose and treated with deoxycholic acid (DOC) to give a final concentration of 0·3 per cent. All figures are usually the mean of 3 individual determinations.

* Too little potassium for determination.

† Mean of six determinations.

Table 1 presents a summary of the results obtained from experiments with liver, kidney, and heart mitochondria. Although results were also obtained for the sodium and potassium contents of the fraction isolated by centrifugation of the mitochondria treated with deoxycholic acid for 20 min. at 25,000*g*, they were not included because this fraction was not homogeneous and probably contained mostly mitochondria which were partially disrupted[6]. The specific activity of the sodium and potassium in this fraction ranged from 0·19 to 4·87 and from 0·15 to 1·98, respectively.

The results in Table 1 demonstrate that the specific activity of sodium in the membrane fractions from all three kinds of mitochondria treated with deoxycholic acid was 2–12 times greater than that in the intact mitochondria. The specific activity of potassium, however, was 1·5–10 times greater in the fresh intact particles than in the membrane fractions. Washing the membrane fraction once or twice with isotonic sucrose (Exps. 8 and 11) appeared to remove little, if any, potassium or sodium. In four experiments, a comparison was made between the ion contents of membrane fractions obtained from 0·3 per cent and 0·5 per cent (or 0·6 per cent) particles treated with deoxycholic acid since the higher concentration has been found to result in closely apposed membranes in contrast to the vesicular elements observed in the electron microscope after treatment with 0·3 per cent deoxycholic acid[6]. The results showed (Exps. 2, 3, 7, and 10) that the specific activity was significantly increased, generally more so for sodium than for potassium, with 0·5 per cent deoxycholic acid. Part of this increase in specific activity was probably a result of the decreased dry weight of the membrane fraction after treatment with 0·5 per cent deoxycholic acid, the average dry weights decreasing from 12·6 to 7·8 mgm. for liver, from 17·4 to 10·7 mgm. for kidney, and from 13·6 to 11·6 mgm. for heart.

In order to determine whether the increase in the potassium gradient, which occurs when mitochondria are incubated in a medium to which an adenine nucleotide and oxidizable substrate are added, is due to an increased amount of the ion in the membrane fraction or in the rest of the mitochondrial water, kidney mitochondria were incubated in a medium (0·25 *M* sucrose, 0·005 *M* magnesium sulphate, 0·005 *M* potassium phosphate buffer, *p*H 7·4, 0·005 *M* sodium phosphate buffer, *p*H 7·4) with or without the addition of 0·001 *M* adenosine triphosphate and 0·02 *M* α-ketoglutarate. After 20 min. incubation in air at 37°, deoxycholic acid was added to half the mitochondrial suspensions to give a final concentration of 0·3 per cent and the membrane fraction was isolated as described previously. Untreated suspensions were centrifuged[1] to separate the intact mitochondria from the suspending medium. The results showed that the potassium gradient:

$$\frac{\text{m.equiv. potassium/litre mitochondrial water}}{\text{m.equiv. potassium/litre suspending medium}}$$

increased from 1·56 to 2·83 when adenosine triphosphate and α-ketoglutarate were added to the medium, the specific activity of potassium increasing from 1·72 to 2·97 (Exp. 9). Since the specific activity of the membrane fraction of the two groups was practically the same, this experiment demonstrates that the increased potassium which is accumulated does not concentrate in the membrane. The rather small difference in specific activity between the intact mitochondria and the membrane fraction in this experiment may be a consequence of suspending the particles in a relatively potassium-rich medium for incubation.

The deoxycholic acid used in these experiments contained considerably less than 1 μgm. potassium/1 ml. solution, but it did contain 5 μgm. sodium/1 ml. solution. Since the total sodium in the membrane fraction was usually 5–15 μgm., a significant error would be introduced into the calculation of specific activity if some or all of the sodium from the acid became attached to the membrane fraction. In attempting to demonstrate that the differences in sodium concentration between the intact mitochondria and the membrane fraction were not an artefact, liver mitochondria suspended either in water or 0·25 *M* sucrose were subjected to ultrasonic vibrations for 1–5 min. in a 10 kc./s. Raytheon sonic oscillator at 250 watts and 1·25 amp. The ultrasonically treated particles were centrifuged for 20 min. at 25,000*g* and the resulting supernatant was centrifuged for 1 hr. at 105,000*g* to isolate a membrane fraction[6,7]. Although mitochondrial membranes isolated from sonically disrupted mitochondria apparently are not pure, in that matrix adheres to the membrane vesicles[5], the inhomogeneity of the membrane fraction probably would not affect markedly the specific activity of the sodium, especially since it is so low in the intact mitochondria. The results, although quantitatively different (Exps. 5 and 6), tended to confirm those obtained with deoxycholic acid. The very low potassium specific activity of the intact water-suspended mitochondria (Exp. 5) was undoubtedly due to leakage of the ion from the swollen particles since the supernatant after isolation of the mitochondria contained very much larger amounts of the ion than were found in the supernatant of 0·25 *M* sucrose-suspended mitochondria.

The data obtained from this work may provide an explanation for the observation that when muscle mitochondria are aged, the potassium content decreases approximately 50 per cent, whereas the sodium content remains virtually unchanged[1]. The decrease in potassium might be explained if one assumes that the small quantity of membrane potassium is firmly bound (see Exps. 8 and 11), while the rest of the mitochondrial potassium is either not bound or is bound to compounds which leak out of the particles during ageing. Since most of the mitochondrial sodium appears to be concentrated in the membrane fraction, ageing would not affect it, if one again assumed that it was tightly bound. In this connexion, the sodium and potassium in the membrane fraction of mitochondria aged for four days by suspending them in 0·25 *M* sucrose at 0° do not appear to change significantly (Exps. 4 and 12).

Whether the differences in sodium and potassium concentration in the mitochondrial membrane fraction have any connexion with the inability of muscle[1] and liver[2] mitochondria to transport sodium against a concentration gradient cannot be assessed at the present time. Further work on this problem is in progress.

This investigation was supported by grants from the National Institute of Arthritis and Metabolic Diseases and the American Heart Association. I am grateful for the very skilful technical assistance of Mrs. Patsy L. S. Smith and Mr. Arthur Nathanson.

Antigonadotropic Function of the Pineal Gland and the Oxytocin of the Neurosecretory Hypothalamic System

THE existence of an active substance in the pineal gland capable of inhibiting gonadotropic hormones is supported by most authors who have studied this problem. On the other hand, nothing has been revealed concerning the mechanism which causes this inhibition. The existence of a direct interaction between the pineal-inhibiting factor and gonadotropic hormones does not seem likely. In connexion with investigations carried out on anti-androgenic fractions of bovine pineal gland, one of us claimed that the antigonadotropic function of the pineal gland was exerted at the level of the subcortical centres inhibited by it[1].

On the other hand, the work of Shibusawa *et al.*[2] and Martini *et al.*[3] seems to indicate that oxytocin represents the releasing factor for gonadotropic hormones.

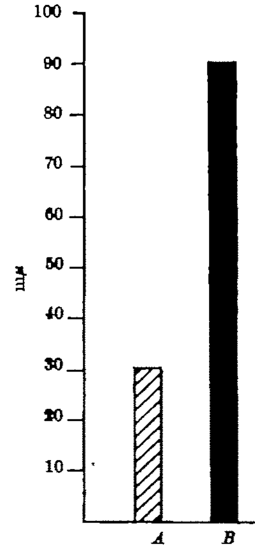

Fig. 1. Oxytocic activity of dog paraventricular nucleus (mean values of 6 animals). *A*, normal activity (30 ± 9 mμ); *B*, 5 hr. after administration of pineal extract (90 ± 12 mμ). The means and their standard errors are given as mμ, in terms of U.S. Pharmacopoeia reference standard

If this hypothesis is correct, the antigonadotropic function of the pineal gland ought to be exerted through the blocking of the oxytocin as a releasing factor in the nuclei of the neurosecretory hypothalamic system.

Our experiment was performed on 12 adult male dogs weighing about 15 kgm. The animals were divided into 2 groups: 6 animals served as controls and another 6 were given intravenous injections of 10 ml. protein extract of bovine pineal gland containing a nitrogen equivalent of 0·03 mgm./ml. The animals were killed 5 hr. after the administration of the pineal extracts, with as little psychic disturbance as possible, by the rapid intravenous injection of magnesium as a 25 per cent w/v aqueous solution of the sulphate. The whole brain and pituitary body were removed in about 10 min. and placed in 20 vol. of anhydrous acetone. The supra-optic nuclei, the paraventricular nuclei, the tuber cinereum and the neurohypophysis were isolated. Extraction was performed according to the method of Van Dyke *et al.*[4]. Holton's method[5] was used for the assay of oxytocin. All determinations were performed in comparison with U.S. Pharmacopoeia posterior pituitary reference standard.

The normal amounts of oxytocin that we found in the paraventricular nucleus is in strong agreement with those of Van Dyke *et al.*[4].

Five hr. after the intravenous administration of 10 ml. protein extract of bovine pineal gland, the oxytocic activity of the paraventricular nucleus increased from 30 ± 9 to 90 ± 12 mμ (Fig. 1). We consider this increased concentration of oxytocin to be due to blocking of this polypeptide under the action of the pineal extract.

In a recent paper[6], a very low oxytocic activity was described in the nuclei of the neurosecretory hypothalamic system during the releasing of gonadotropic hormones. In the present work, concomitantly with the blocking of gonadotropic hormones, there is a significant increase of the oxytocic activity in the nuclei of the neurosecretory hypothalamic system. This parallelism between the releasing or blocking of gonadotropic hormones and releasing or blocking respectively of oxytocin in the neurosecretory hypothalamic system supports the hypothesis of Shibusawa and Martini according to which oxytocin or an active substance associated with it represents the releasing factor for the gonadotropic hormones. On the other hand, this experiment shows that the antigonadotropic function of the pineal gland is achieved through blocking of the oxytocin or of an active substance associated with it in the neurosecretory hypothalamic system, and not through the direct interference with gonadotropic hormones. The antigonadotropic function of the pineal gland is in fact an antigonadotropic hormone function. This hypothesis is strongly supported by Milin's histophysiological investigations[7]. He found a lowered activity of the nuclei of the neurosecretory hypothalamic system in the rabbit during the blocking of the gonadotropic hormones by darkness and an increased activity of these nuclei during the releasing of gonadotropic hormones caused by light. In the first case, the pineal gland is hyperactive, in the second hypoactive. Investigations which are under way concerning the action of pineal extracts on vasopressin in the neurosecretory hypothalamic system make us assume that the anticorticotropic function of the pineal gland is exerted through the intermediary of vasopressin as a releasing factor of a substance associated with it, and not through the direct interference with adrenocorticotropic hormone.

Thus, it seems that the antigonadotropic mechanism consisting in the blocking of releasing factors represents a general pattern according to which the pineal gland exerts its antitropic functions. Investigations now being carried out will, we hope, furnish new data on the relationship between tropic hormones and the releasing factors in the neurosecretory hypothalamic system.

Autonomic Nerve–Smooth Muscle Transmission

Despite extensive work on the morphology and pharmacology of autonomic effector systems, very little is known about the mechanism of transmission of excitation from nerve to smooth muscle. In the present work our approach has been to apply modern electrophysiological methods to a suitable autonomic nerve–smooth muscle preparation in a manner similar to that described for the skeletal neuro-muscular junction[1].

Smooth muscle cells from the longitudinal layer of the vas deferens of the guinea pig were impaled with capillary microelectrodes and membrane potential

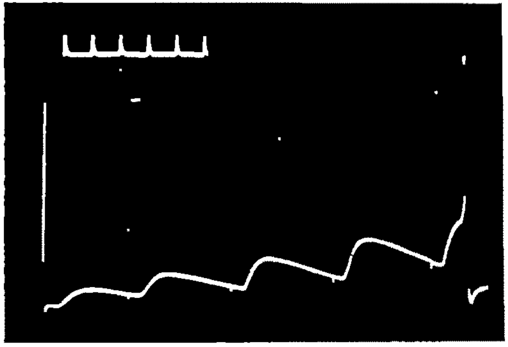

Fig. 1. Membrane potential recorded from a single smooth muscle fibre of the vas deferens of the guinea pig during repetitive stimulation of the hypogastric nerve (stimuli 1 msec. duration). Successive 'junction potentials' increase in amplitude and rate of rise. Summation occurs until at a critical depolarization a spike is initiated

changes recorded during repetitive stimulation of the hypogastric nerve. The vas deferens was never spontaneously active. In the experiment illustrated in Fig. 1, the resting potential was 65 mV. Five successive stimuli resulted in depolarizations of progressively greater amplitude until, at a critical membrane potential (37 mV.), a spike was initiated and a vigorous contraction occurred. The membrane potential at which the spike arose was remarkably constant for the majority of cells (35–38 mV.). The number of stimuli required to reach this threshold, however, was variable.

The mean resting potential of the vas deferens was 57 mV. ($SE_M = 6$ mV.). The spike was similar in configuration to those recorded from the taenia coli of the guinea pig[2] and the uterus of the rat[3]. Spike amplitudes of up to 84 mV. were recorded (mean 68 mV., $SE_M = 8$ mV.); overshoots were up to 20 mV. The positive phase of the spike (after-hyperpolarization) generally brought the membrane potential back to, or beyond, its resting-level.

We have decided to call the successive depolarizations in response to nerve stimulation 'junction potentials'. We felt that the term 'end-plate potential' was best reserved for tissues where a definite end plate region could be distinguished; the term 'post synaptic potential' did not seem appropriate since, at present, there is no histological evidence for any structure resembling a neuronal synapse in smooth muscle.

Both the amplitude and the rate of depolarization of the junction potentials increased with successive stimuli, this facilitation occurring even when the interval between stimuli exceeded 500 msec. The rate of depolarization of the junction potential was slow compared with other post-synaptic potentials. The rate of decay of the junction potential varied greatly from preparation to preparation. We think it is unlikely that this slow decay is dependent on the time-constant of the membrane, but that it may represent slow destruction of the transmitter. Brown and Gillespie[4] suggested that at least 100 msec. were required for destruction of the noradrenaline released from cat spleen by splenic nerve stimulation.

Junction potentials could be recorded in cells along the entire surface of the vas deferens. Their amplitude and latency varied somewhat from cell to cell, but there was no indication of a defined end-plate region. The functional distribution of nerve endings therefore appears to resemble that of crustacean muscle[5]. The amplitude of the junction potentials was dependent on the number of nerve fibres stimulated. If the hypogastric nerve was stimulated submaximally, the amplitude of junction potentials all over the muscle was reduced.

In the absence of nerve stimulation small 'miniature junction potentials' were recorded which presumably indicated the spontaneous release of transmitter. Their frequency was lower than that observed at the skeletal neuromuscular junction[6]. Their amplitude was larger (up to 18 mV.); but this may be accounted for in terms of the small diameter of the muscle fibres[7].

The response of the vas deferens to hypogastric nerve stimulation was unaffected by hexamethonium (5×10^{-6}) and atropine (10^{-6}), but was blocked by the anti-adrenergic drug darenthin (5×10^{-6}). Thus, stimulation appears to have been post-ganglionic and the transmitter is most likely to be noradrenaline.

These results will be published in detail elsewhere.

We wish to thank Dr. Michael Rand for introducing us to this preparation and for assisting us with the pharmacology.

PSYCHIATRY

Paradoxical Blocking and Arousal in the Drowsy State

THERE have been many attempts to investigate the hypnotic state making use of the electroencephalograph. Though clinically the subject might have the appearance of sleep, the electroencephalograph was not found to be different from that found in the wide-awake hypnotized state. Darrow *et al.*[1] believed that the electroencephalograph in hypnosis had characteristics that distinguished it from both true sleep and full consciousness. Our experience does not confirm either of these views, but we have not found the electroencephalograph of a hypnotized person to have any distinctive characteristics. Rather the electroencephalograph of the hypnotized person can be characteristic of the waking or drowsing electroencephalogram without hypnosis, depending upon the situation and the suggestions given. This finding is therefore in accord with those of older writers on the subject, including Paul Schilder[2].

In the case we are describing, the patient had been hypnotized several times. Suggestions were given to "Allow yourself to go deeper and deeper asleep . . ." with explanations to the effect that the word 'sleep' was here being used in a special sense, because the subject was told that he could still hear and comprehend the experimenter. On other occasions he was urged to go to sleep and become "oblivious to everything and be completely relaxed". On one such occasion when the record gave evidence of drowsiness

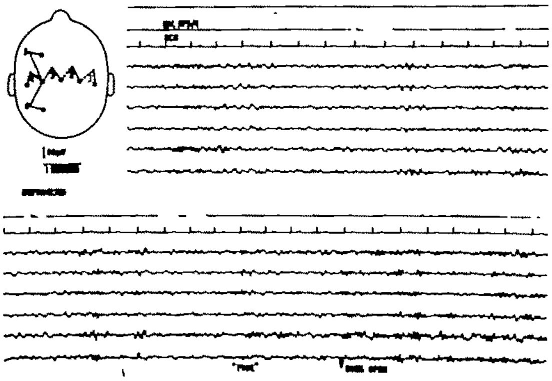

Fig. 1

(in this instance for 40 sec.) it was suggested that after the experimenter had counted from 1 to 5, he would be able to open his eyes. No change in the electroencephalograph occurred during counting or while the instruction was being given. Three seconds after the count of 5 the patient opened his eyes and there was at this time paradoxical blocking of the alpha rhythm (that is, the alpha appeared on eye opening). Despite the fact that the instruction was obeyed, arousal from the drowsy state, as illustrated by the electroencephalogram, did not occur until the patient actually opened his eyes. Therefore opening the eyes was the first external change observed, and the electrical change coincided with this. Since the instruction was obeyed, one would have expected the record to change while the instruction was being given. On other occasions different tasks had been set, to be obeyed on counts of 3 or 5; it is therefore unlikely that on this occasion the correct response was a chance occurrence. There was one other occasion when the patient was instructed to rub his face with his hand after a count of 5. During the instruction the record was that of drowsiness, but when he started to rub his face some 6 sec. after the count of '5', the alpha rhythm appeared. The alpha rhythm here is therefore an index of arousal. The arousal occurred when the instruction was obeyed and not when it was given. This is of interest in view of the finding by Oswald *et al.*[3] that in light sleep *K*-complexes occurred more often to certain names, especially the subject's name, rather than to meaningless sounds. They concluded that the censorship controlling arousal was in the cortex. On the other hand, our example seems to pose again the question asked by Adrian[4]: "If patterns arrive at the cortex, who reads the patterns?" Adrian[4] also said, "The meaning of the stimulus is there before the mind comes to understand it". Our example perhaps supports this statement, the instruction having been received and then apperceived, and the stimulus for arousal comes into being as a result of the significance of the instruction for the sleeper. We would agree more with Adrian[4] that the diencephalon is mostly concerned. "The physical intensity of the stimulus is not as important as the emotional associations"[5]. This statement is supported by our observation. The instruction is received and the mechanism of response put in train (? understood). Electroencephalograph arousal, when it occurs, is not therefore to the auditory stimulus of the instruction given nor to the internal mechanism set in train to provide the ultimate response, but takes place when this response occurs. Arousal is then a response to the emotion evoked by the performance of the act itself and the meaning of it to the sleeper.

RADIOBIOLOGY

Dye-sensitized Photo-reactivation of X-ray Damage in Diploid Yeast

In an investigation of the binding of amino-acridine dyes to deoxyribonucleic acid in living cells we have shown that the nucleic acid fluorochrome, acridine orange (3,6,-*bis*-dimethylaminoacridine), sensitizes both haploid and diploid yeast (*Saccharomyces cerevisiae*) to visible light[1]. The significance of the survival curves obtained for this acridine orange-sensitized photo-inactivation was further examined by experiments involving additivity of X-rays, ultra-violet and visible light. In the course of these additivity studies[2] a new effect appeared: dye-sensitized visible-light reactivation of X-ray damage in diploid cells. This effect is of special interest because, although ultra-violet damage having a nucleic-acid action spectrum is partially reversible by visible light, previous attempts at reactivation of X-ray damage with visible light have not been successful[3].

The techniques for handling and irradiating the yeast have been described elsewhere[4]. In the present experiments cells which had grown for seven days at room temperature on potato dextrose agar were suspended in *p*H 7 phosphate buffer to make a final concentration of 10^6 cells/ml. This suspension was exposed first to a dose of X-rays (dose-rate 330 r./min.) sufficient to inactivate a predetermined fraction of the population. Then purified acridine orange (1 : 2,000) was added to make a final dye concentration of 1 : 200,000 or $1 \cdot 8 \times 10^{-6}$ *M*; after 20 min. in the dye the cells were irradiated with visible light (10^4 ergs/cm.^{2}/sec.). The light source was a General Electric *R*-52 750-watt flood lamp. The output of this lamp was filtered through a copper sulphate solution and a Corning filter No. 3389 to remove infra-red and near ultra-violet components which cause inactivation in the absence of the dye.

The results of a typical experiment are shown in Fig. 1. Here, the suspension was irradiated with X-rays until 85 per cent of the original population was inactivated (that is, to the 15 per cent survival-level). (Similar results are obtained for both lower and higher levels of survival.) In all cases, subsequent irradiation with low doses of visible light (in the presence of dye) increases this surviving fraction, thus indicating a repair or by-pass of part of the damage produced by the X-rays. With increasing dose, simultaneous killing by the visible light first lessens and finally overrides the observed reactiva-

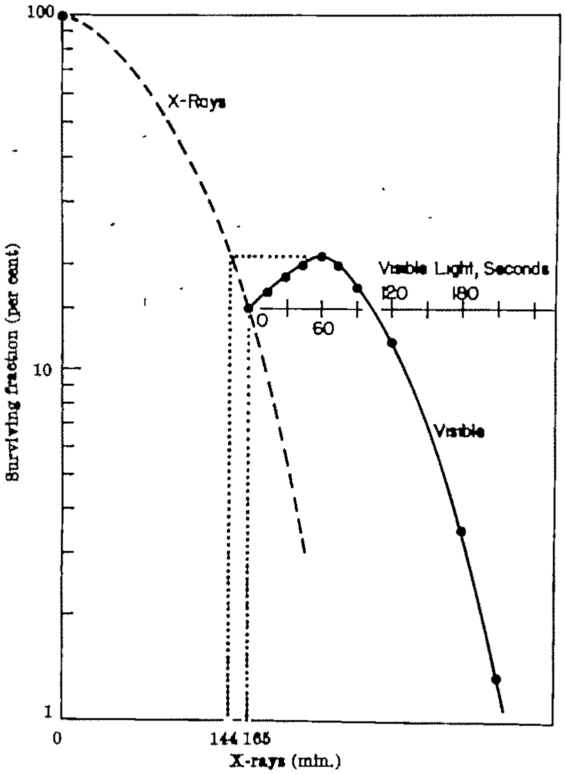

Fig. 1

tion. At the apparent maximum (60 sec.), the dose reduction factor for X-ray damage is 165/144 = 1·14. The actual maximum degree of reactivation is probably much higher and could ordinarily be determined graphically by subtracting the normal visible light inactivation curve, were it not for the quantitatively unknown degree of additivity of X-rays and visible light. (The visible light inactivation curve which would occur in the absence of reactivation is steeper than the ordinary curve for a non-pre-irradiated population because of the existence of common sites for X-ray and visible light damage.)

This reactivation of X-ray damage is not found in haploid yeast. Since the dye-sensitized visible light survival curve for haploid cells surviving X-irradiation is identical with that for non-pre-irradiated cells, there is not only no increase in survival, but also no interaction of the two irradiations at all. This lack of haploid reactivation suggests some difference between the inactivation process for the two ploidies that is not necessarily associated with simple genetic duplication. Clearly, either the reactivable site in the diploid accounts for, at most, a very small part of the X-ray damage in the haploid (which implies some independence in the X-ray sites of the haploid and diploid), or the site is present in both haploid and diploid; but, because of some difficulty in the dye-binding or sensitization process, it is not reactivable in the former. It is difficult to separate these possibilities, since from additivity and survival experiments we have been able to conclude only that for X-rays and visible light (with dye) some of the haploid sites are also diploid sites and some of the X-ray sites are also visible sites; we have not yet been able to determine the degree of overlap or to equate one part with another. Reactivation by visible light involving a dye which binds deoxyribonucleic acid nevertheless strengthens the view that part of the X-ray damage to a cell is damage to deoxyribonucleic acid molecules.

It has been reported that X-ray damage in yeast can also be repaired, in part, by ultra-violet light[5]. In this case, also, there is a decreased effect in the haploid, although in a genetically related non-respiring haploid the effect is the same as in the diploid. However, since ultra-violet reactivation of X-ray damage is found only with actively budding cells rather than the resting cells used in the present work, a comparison is probably not valid, especially since there are striking differences in the X-ray curves for resting and budding populations[6].

This investigation was aided by research grant C-2739 from the National Cancer Institute of the United States Public Health Service. One of us (D. F.) was supported by a National Science Foundation pre-doctoral fellowship.

Influence of Localized Ultra-violet Irradiation on the Incorporation of Adenine-8-^{14}C and D,L-Methionine-^{35}S in *Acetabularia mediterranea*

We have shown recently[1,2] that methionine labelled with sulphur-35 is incorporated in a decreasing apico-basal gradient in the unicellular alga *Acetabularia mediterranea*. The existence of this gradient suggested a possible relationship between methionine incorporation, ribonucleic acid metabolism and the production of morphogenetic substances in this alga. We have now examined the effects of localized ultra-violet irradiation, delivered to algal stem tips or rhizoids, on morphogenesis and adenine and methionine incorporation, in order further to evaluate the reality of this relationship and its implications.

The present observations were made on whole algae shortly before cap formation. Irradiations were limited to either the first 3 mm. of stem tip or the rhizoid. The ultra-violet dose applied was equivalent to 8 × 10^{3} ergs/mm.[3]. This dose, while effective, produces no demonstrable lethality[3]. Incubation with labelled precursors (adenine-8-^{14}C at 0·1 μc. and 0·02 μM/ml., D,L-methionine-^{35}S at 0·1 μc. and 0·002 μM/ml.) occurred over a 48-hr. period immediately following irradiation. Incorporated radioactivity was detected autoradiographically by the methods described by Ficq[4].

While some retardation and partial inhibition of morphogenesis was noted regardless of the point of irradiation, the inhibition of cap formation was considerably more pronounced when the tip was irradiated (about 50 per cent) than when the irradiation was restricted to the rhizoid (about 14 per cent inhibition). Quantitative analysis of the autoradiographs of unirradiated algae showed an adenine-^{14}C incorporation gradient which was qualitatively similar to that observed with methionine[3,4], but which differed in sharpness; methionine incorporation was ten times more intense in tip cytoplasm than in the cytoplasm of the rhizoid; the adenine incorporation ratio between the two morphological extremities was only 3 : 1.

Irradiation of the rhizoid led to a marked reduction (about 50 per cent) in the incorporation of both adenine and methionine, without modifying the characteristic apico-basal gradients of either; the inhibition produced by rhizoid irradiation was thus a general one. Irradiation of the stem tip, however, resulted in a specific inhibition of adenine and methionine incorporation in the irradiated region; the cytoplasm of the rhizoid was even more strongly labelled after stem tip irradiation than in control algae.

These results suggest that the rhizoid, or more probably the nucleus which is located there, exerts a control, direct or indirect, on the synthesis of ribonucleic acid[5] and that of sulphur-containing proteins[1,2]; these proteins and ribonucleic acid accumulate in the apical extremity of the alga. Ultra-violet irradiation restricted to the apical region inhibits both morphogenesis (that is, cap development) and the accumulation of these substances at the stem tip. These new results provide further support for the notion that ribonucleic acid and sulphur-containing proteins play an important part in the morphogenesis of *Acetabularia mediterranea*[6].

Identification of Transplanted Bone Marrow Cells in Radiation Chimæras

THE beneficial effect of bone marrow transfusion in acute radiation syndrome is now well established. This effect seems to depend on the survival of transfused cells and their proliferation in the depleted hæmopoietic tissues of the recipient[1]. In view of this, there arises the problem of identification of donor cells. Various methods were devised to this end, each permitting the recognition of a certain percentage of a particular cell series[1].

The purpose of this work was to find if rabbits, complete heterozygous carriers of the Pelger anomaly, may be used as donors and if transfused cells may be identified by their characteristic morphological appearance. This consists in specific structure of chromatin in all nucleated blood and bone marrow cells, early blast stages and orthochromatic erythroblasts excepted. Moreover, the granulocytes and megakaryocytes are characterized by hyposegmentation of their nuclei[2].

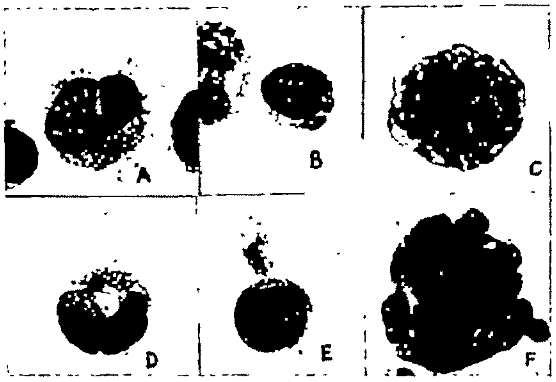

Fig. 1. A comparison between Pelger and normal bone marrow cells. Pelger cells: *A*, Metamyelocyte; *B*, polychromatic erythroblast; *C*, naked megakaryocytic nucleus; *D*, *E*, *F*, normal counterparts. Photomicrograph from a bone marrow smear from a radiation Pelger chimæra

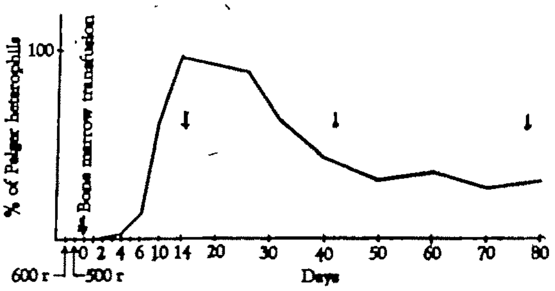

Fig. 2. Curve representing the percentage of Pelger heterophils in the peripheral blood of a Pelger radiation chimæra. 100 per cent = all heterophils in the blood. Arrows indicate bone marrow biopsy

39 rabbits were exposed to total-body X-irradiation (1,100 r.: initial dose of 600 r., followed after 24 hr. by 500 r.). To 5 rabbits an injection of bone marrow cell suspension obtained from Pelger rabbits was administered; 16 animals (males) were injected with bone marrow cell suspension from female donors according to the technique described by Porter[3]. The remaining rabbits served as controls, their mean survival-time being 10 days.

In the first experimental group all donors exhibited Pelger traits in all nucleated blood and bone marrow cells, especially in the granulocytic erythroblastic and megakaryocytic series (Fig. 1), with the above-mentioned exceptions. All recipients were examined beforehand for the presence of Pelger traits, because of the frequent occurrence of partial carriers among rabbits[2]. Following successful bone marrow transplantation, donor cells could be easily identified in peripheral blood (especially heterophils, Fig. 2) of the recipients. We obtained two rabbit-radiation-Pelger-chimæras, which survived longer than 30 days. Fig. 2 illustrates the findings in one of these (peripheral blood). Donor cells could be identified also in the bone marrow, which may be illustrated by the findings of bone marrow biopsy performed the fourteenth day on the same animal, as in Fig. 2.

Table 1

Cell series (per cent)	Granulocytic	Erythroblastic	Megakaryocytic
Pelger (donor) cells	82	46	46
Host's cells	8	34	33
Unidentified cells	10	20	21

In the second experimental group the transfused cells were identified by the presence of sex chromatin in heterophils, as described by Porter[3]. This group served as controls for the Pelger group, showing a similar survival-time. The time-course of increase in donor cells in the blood of the recipients was also similar, although the percentage of Pelger cells was much higher.

We believe that this method for the identification of transplanted bone marrow cells may be useful in experiments on rabbits, making it possible to follow the course of cytological changes during the recovery period in the bone marrow and peripheral blood as well. Moreover, this method may be applied for the simultaneous identification of all three donor bone marrow cell series and is more convenient than former methods.

We wish to express our thanks to Dr. E. Undritz, of the Sandoz Laboratories, for kindly supplying Pelger rabbits.

Urinary Excretion of β-Amino-*iso*butyric Acid after Injection of Thymidine labelled with Tritium

β-AMINO-*iso*BUTYRIC acid is a metabolic degradation product of thymine[1,2], but its relation to the catabolism of endogenous deoxyribonucleic acid has remained uncertain. In the present communication we present results which elucidate the catabolic fate of that fraction of thymine originating from endogenous deoxyribonucleic acid and reflected in the urinary excretion of β-amino-*iso*butyric acid.

Each of five rats weighing 130 gm. was injected intraperitoneally with $4 \cdot 5 \times 10^7$ c.p.m. of ^{3}H-thymidine in three equal doses given at 3-hr. intervals. The ^{3}H-thymidine used was prepared as described previously[3]. Pooled urine samples were collected from these animals during successive 24-hr. intervals throughout the 30-day experimental period. The rats were killed at various times after the injection of ^{3}H-thymidine. Deoxyribonucleic acid was isolated from several organs, as described previously[3], and β-amino-*iso*butyric acid from the urine specimens. A new method was used to determine β-amino-*iso*butyric acid[4]. This involved the initial conversion of β-amino-*iso*butyric acid to its dinitrophenyl derivative and the quantitative chemical determination thereof on the basis of the optical density at 360 mμ. Radioactivity of this dinitrophenyl derivative was determined in the manner described previously[3] using a gas-flow counter. The error involved in the determination of the specific activity of urinary β-amino-*iso*butyric acid was of the order of 10 per cent.

A plot of the specific activity of β-amino-*iso*butyric acid *versus* time is presented in Fig. 1. As can be seen, the specific activity decreased rapidly during the initial three days but only gradually thereafter. Presumably, the marked initial decrease in the specific activity results mainly from the utilization of thymidine for biosynthesis of deoxyribonucleic acid or degradation of thymidine *via* dihydrothymine and β-amino-*iso*butyric acid. Since on the second day the specific activity of tissue deoxyribonucleic acid exceeds that of urinary β-amino-*iso*butyric acid it appears reasonable to assume that at this time the breakdown of deoxyribonucleic acid contributes significantly to the labelling of β-amino-*iso*butyric acid. The rapid replacement of labelled deoxyribonucleic acid of intestine and hæmatopoietic tissue is thought to cause the initial decrease in the specific activity of urine. In other organs, such as liver or muscle, replacement of deoxyribonucleic acid is slower and may contribute radioactivity to β-amino-*iso*butyric acid at the later time period. The specific activity of deoxyribonucleic acid isolated from several organs on the third day is cited here for the purpose of comparison with the specific activity of β-amino-*iso*butyric acid, namely, liver, 2,800, muscle, 3,300, intestine, 7,400, and spleen, 6,300. The specific activity of intestinal deoxyribonucleic acid 24 hr. after injection of thymidine was 34,000. All values represent c.p.m./μmole of thymidine.

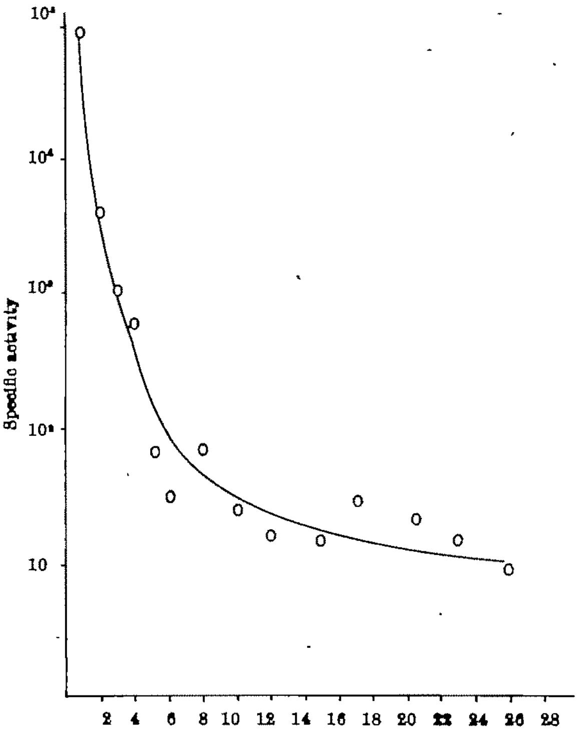

Fig. 1. Plot of specific activity *versus* time of urinary β-amino-*iso*butyric acid. The specific activity is expressed as the logarithm of c.p.m./μmole and time in days

Since ^{3}H-thymidine may undergo exchange reaction during the metabolic conversion to β-amino-*iso*butyric acid, the fraction of thymidine which participates in the synthesis of deoxyribonucleic acid cannot be assessed quantitatively, although this could be accomplished by using thymidine labelled suitably with carbon-14.

Two other radioactive compounds were detected in the urine of these rats. One of these has been identified tentatively as dihydrothymine and resembles β-amino-*iso*butyric acid with respect to its curve of specific activity *versus* time. The second compound has not been identified as yet.

This work was supported, in part, by the United States Atomic Energy Commission.

BIOLOGY

Electrical Sensitivity of the Ampullæ of Lorenzini

Electrophysiological investigation has shown that the ampullæ of Lorenzini of elasmobranch fishes are sensitive both to slight changes of temperature[1] and also to weak mechanical stimuli[2]. But neither sensory modality is convincing as the biologically adequate stimulus, for the temperature-sensitive regions are buried deep in the body (there being no apparent reason for the great anatomical development of the tube system), and the mechanical sensitivity is quantitatively less than that of the lateral line without being qualitatively very distinct.

There is, however, a third possibility. I have found that in rays the ampullæ are sensitive to slight changes in the electrical potential field surrounding the fish (*Raia clavata*, *R. naevus*, *R. montagui* and *R. brachyura* were used). The impulse discharge from single units in the mandibular group of ampullæ was recorded with the fish submerged about 1 cm. in a large dish of sea water; voltage gradients in the water over the sense organs were established from electrodes near the tail. Under such conditions the threshold d.c. potential gradient (that is, which produced approximately 10 per cent change of impulse frequency at make and break) was 1–2 μV./cm. (8 fish). The gradient had to lie along the line of the tubes, with the opening of the tubes negative to the capsule for an increase in frequency, and the opening positive for decrease. In each case there were opposite after-effects at break. The adaptation was almost complete, with a time-constant of about 5 sec. as is found with direct galvanic polarization of the sensory nerves[3].

With the preparation out of water, the ampullæ could be stimulated by passing a current between a small test probe and the body of the fish. When the probe was placed exactly on the opening of the tube from which the single fibre of the recording ran, a current of 0·005 μamp. (the smallest which could at the time be measured) was considerably greater than threshold; the frequency was increased when the probe was cathodal. But if the probe was displaced slightly from the opening, for example, by 0·5 mm., the threshold became far higher. Thus the stimulating currents would appear to be channelled along the jelly-filled tubes. In this connexion the conductivity of the jelly has been shown (Murray, R. W., and Potts, W. T. W., unpublished work) to be high (85–90 per cent of sea water) compared with that of the body fluids (40–45 per cent of sea water) and presumably the tissues have an even lower conductivity.

There would seem to be at least three possible ways in which this electrical sensitivity could be of direct use to the fish.

(1) It is known that rays have small electric organs derived from part of the tail musculature[4] which produce second-long pulses of up to 4 V. The potential gradients resulting from these would be at least 1,000 times stronger than those which I have found to be threshold for the ampullæ. Lissmann's suggestion[5] is therefore feasible, that this system could act as a navigation device, with the ampullæ detecting the changes in the field produced by the electric organs when an object with a conductivity different from the sea water comes near the fish. The ampullæ could of course act as the receptors for such a navigational system only in elasmobranchs, as they are not found in the teleosts with electric organs.

(2) I have some evidence that the ampullæ are sensitive to changes in the salinity of the sea water at their openings of about 5 per cent. The mechanism for this sensitivity could be electrical, depending on the differences in the diffusion potentials caused by dilution.

(3) When a conductor is moved through the Earth's magnetic field, potential gradients are set up in it. Under certain conditions it is possible to detect by this means the strength and direction of a tidal stream or ocean current. It is, however, theoretically improbable that a fish being carried along by the water movement, and therefore subject to the same influences, could detect these small potentials, although it might be able to determine whether the current was, for example, easterly or westerly by swimming up from a position at rest on the bottom.

Development of Delayed-type Hypersensitivity in Guinea Pig Embryos

Several modalities of the immune response of embryos have been previously investigated. These include: (*a*) induction of immunological tolerance[1]; (*b*) antibody formation[2]; (*c*) capacity to reject homografts[3]. There have been no analogous studies of the capacity of the embryo to develop the delayed type of hypersensitivity to protein antigens.

Previous attempts to induce tuberculin skin reactivity in new-born guinea pigs by active sensitization[4] or by passive transfer with leucocytes[5] have been unsuccessful. Weiss[6] injected guinea pig embryos with tubercle bacilli, and elicited tuberculin reactions in some of these animals several weeks after birth.

In the present work, guinea pig embryos were injected *in utero* usually 1–2 weeks before the expected date of their delivery. In early experiments, the injections were made after laparotomy. Afterwards, injections were performed through the intact abdominal wall, using a 23-gauge needle directed at the position of the peritoneal cavity of the embryo, which was held between the fingers of the operator's other hand. In this fashion, 1–10 μgm. of protein antigen contained in 0·1 ml. of complete Freund's adjuvant (including killed *Mycobacteria butyricum*) were injected into the embryo. Only two embryos in each litter were injected, since more injections greatly increased the rate of abortion. After birth, attempts to identify those embryos which had been injected were unsuccessful, despite the use in several experiments of proteins trace-labelled with iodine-131, and the inclusion of Evans blue dye in the suspension. This failure was probably due in part to the small amount of antigen injected and the slow release of the injected material from the saline-in-oil suspension. New-born guinea pigs were usually skin-tested on the first day of life with 3 μgm. of specific antigen. If the sensitizing injection had been administered less than five days before delivery, the skin testing was postponed until five days after sensitization.

Delayed-type reactions to diphtheria toxoid, ovalbumin, or bovine serum albumin similar to those previously described in adult animals[7] were elicited in 31 new-borns during the first five days of life. The average diameter of the reactions varied from 11 to 23 mm. Since a total of 83 injections were attempted in the embryos that survived, the sensitive animals probably represent a minority of those injected. Four skin reactions at 18–24 hr. and one reaction at 48 hr. after intradermal challenge were biopsied. Histological examination revealed pronounced infiltrations of lymphocytes, histiocytes and a smaller number of polymorphonuclear leucocytes throughout the dermis and subcutaneous tissue with an absence of vasculo-necrotic lesions (Fig. 1). Such lesions are typical of 'tuberculin-type' skin reactions[8].

Almost all the delayed-type skin reactions were obtained in animals weighing more than 90 gm. at birth, although an equal number of new-borns weighed between 50 and 90 gm. Since the weight of new-born guinea pigs is mainly a function of their intrauterine age[9], the capacity of guinea pig embryos to become sensitized probably depends in part on their general maturation.

In order to determine whether lymphoid cells were available in the smaller animals to participate in inflammatory reactions, total and differential white cell counts were carried out on three new-born animals that weighed 70 gm. each, and again on these animals two weeks later when they weighed 132–145 gm. At age one day the average white count was 2,800 with 41 per cent lymphocytes, compared to 4,900 with 65 per cent lymphocytes two weeks later, suggesting that there are an adequate number of lymphocytes in the circulation of the smaller new-born animal.

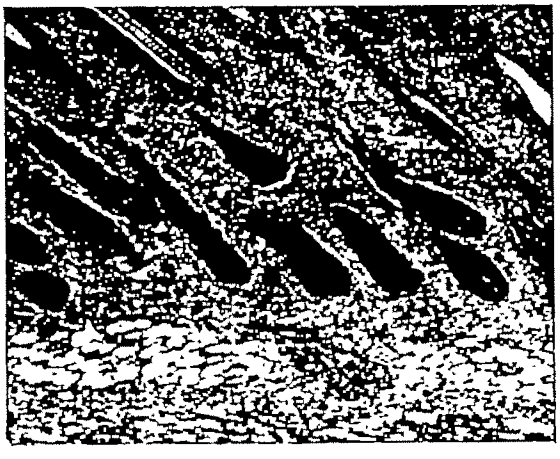

Fig. 1. Delayed-type skin reaction at 20 hr. elicited in a one-day old guinea pig. Haematoxylin and eosin. (× 45)

Table 1. DELAYED-TYPE HYPERSENSITIVITY IN ONE-DAY OLD GUINEA PIGS PREVIOUSLY SENSITIZED *in utero*

Sensitizing antigen	Birth-weight (gm.)	Delayed skin reaction (mm)	Passive cutaneous anaphylaxis test for serum antibody	
			Negative on day	Positive on day
Diphtheria toxoid	104	17 × 18	5	11
	104	11 × 12	11	—*
	94	22 × 25	11	—
	110	13 × 10	—	13
	124	18 × 17	—	11
	112	15 × 15	—	9
	96	15 × 15	—	9
Bovine serum albumin	112	20 × 20	3	6
Ovalbumin	100	17 × 16	2	10
	96	20 × 16	3	8
	88	17 × 18	3	8
	113	23 × 24	3	6

* Not done.

To ensure that delayed-type hypersensitivity in new-born animals was not the result of maternal sensitization and passive transfer across the placenta, twelve pregnant guinea pigs were injected intramuscularly 1–2 weeks before delivery with 1–10 μgm. of ovalbumin or toxoid in complete adjuvant. The new-born animals were skin-tested after their weight reached 100 gm. and none of fifteen animals showed delayed-type reactions.

Table 1 shows the positive skin reactions obtained in one-day old new-born animals in which antibody results using passive cutaneous anaphylaxis were also available. As seen in this table, antibody can be demonstrated in the serum of sensitive animals as early as one week after birth. When diphtheria toxoid was used as the antigen, the same serum in which antibody was demonstrated by passive cutaneous anaphylaxis failed to reveal antitoxin by the neutralization test for diphtheria toxin in rabbit skin. This is probably due to the production of antitoxin of low avidity, rather than to differences in sensitivity or specificity of the two tests. The possibility that antibody was produced against only non-toxoid diphtherial proteins is unlikely, since bovine serum albumin, which is less antigenic than toxoid for guinea pigs, stimulated detectable antibody formation.

To see if all new-born guinea pigs could be sensitized, twelve one-day old animals were injected either intramuscularly or in all four footpads with 1–10 μgm. of ovalbumin in complete Freund's adjuvant. Skin testing with 3 μgm. of ovalbumin 7–10 days later revealed delayed-type reactions in all those immunized in the footpads, but in only three of six immunized intramuscularly. Since the adult animal can be consistently made to acquire delayed-type hypersensitivity by the intramuscular route (if mycobacteria are included) it is possible that the new-born animal is sensitized less readily.

The capacity of one-day old animals to exhibit other hypersensitivity reactions was investigated, because of previous reports of the 'non-reactivity' of the skin of new-born guinea pigs[10]. To sensitize for passive cutaneous anaphylaxis reactions, 1 μgm. of rabbit anti-ovalbumin was injected intradermally into each of two new-born animals. Five hr. later, 1 mgm. of ovalbumin and Evans blue dye were injected intravenously. Blue reactions measuring 10 mm. by 10 mm. and 19 mm. by 17 mm. were obtained, but they were less intense than those simultaneously induced in adult animals. To produce passive Arthus reactions, two new-born guinea pigs were injected intravenously, and two intraperitoneally, with 700 μgm. rabbit anti-ovalbumin followed 24 hr. later by intradermal injection of 30 μgm. ovalbumin. The intravenously sensitized animals developed typical Arthus reactions with maximal intensity at 4 hr., at which time the lesions averaged 45 mm. in diameter with a central hæmorrhagic area measuring 8–10 mm. in diameter. By 24 hr. the lesions had almost completely regressed. The animals sensitized intraperitoneally displayed milder reactions. Large necrotic lesions were also produced in neonatal animals by the intradermal injection of 0·025 MLD. of diphtheria toxin.

Our finding that delayed-type hypersensitivity can be induced in some guinea pig embryos is consistent with the relative maturity of this species at birth.

This work was aided by grants from the National Institutes of Health (*E* 1821 (*C*-2)) and the Commission on Immunization of the Armed Forces Epidemiological Board.

Insects attacking *Striga*

WORKING in Ibadan, Nigeria, Williams and Caswell[1] have recently noted *Smicronyx* sp. (Curculionidae : Coleoptera), the larva of which lives within the fruits feeding on the immature seeds of *Striga* sp. The only other reference mentioned is that of Agarwala and Naqvi[2] on *Striga* in Bihar, India. Williams and Caswell have apparently missed references on the subject, especially that on *Smicronyx albovariegatus* Faust. recorded on *Striga*.

The first published record of an insect attacking *Striga* was that of Murthy and Rao[3], who observed the caterpillars of *Precis orithya* Swinhoeii (Fam. Nymphalidæ, Lepidoptera) feeding on leaves, flower buds and tender fruits of *Striga* in the former Hyderabad State, India. Following the publication of that observation, Uttaman[4] pointed out that during the course of work on *Striga* in Malabar, India, he had noted grubs of a beetle (Sub-fam. Galerucinae) feeding on stem, leaves and the pods. While continuing work on the insect fauna of this root parasite in Hyderabad, I collected *Striga* stem galls in numbers caused by a curculionid weevil grub, and Mani[5], on the basis of the plant material sent from Hyderabad, described briefly the structure of the gall. Work was later initiated on the above insect at the Entomological Laboratory, Government Agriculture Research Station, Rudroor, Hyderabad State, and the weevil was identified as *Smicronyx albovariegatus* Fst. by the Commonwealth Institute of Entomology, London. A brief account of the above insect was afterwards given by Khan and Murthy[6]. The adult weevils appear early in September and galls were noticed from the middle of September until January. A single grub is found in each gall. The number of galls per plant may vary from 1 to 30. When full grown, the grub comes out of the gall and pupates in the soil. The incidence of the weevil varies from 40·7 to 62·0 per cent. The grub not only causes stem galls but also eats into the seed capsules. During later work in Mysore State, another mode of injury caused to *Striga* plants by this weevil was recorded, namely, the formation of root galls by the grub[7]. It was observed that on account of the presence of root-galls there is weakening of the *Striga* plant which may perhaps be due to the impaired absorption of nutrients due to root damage.

Other insects recorded on *Striga* in India are *Monolepta signata* Oliv. (Galerucinae; Chrysomelidae), caterpillars of a *Pterophorid* moth eating into the seed capsules[4,8] and a species of aphid awaiting determination.

While working in the Entomological Division, Government Agriculture Research Station, Rudroor, a detailed investigation was carried out on the possibilities of biological control of *Striga*, which is to be published shortly. It has been found that both *P. orithya swinhoei* and *S. albovariegatus* do exercise certain natural checks on the growth and development of *Striga* in the field. While no natural enemies have been encountered against *S. albovariegatus*, I have recorded[9] the caterpillars of *P. orithya swinhoei* being attacked by the tachinid endoparasite, *Sturmia* (*S. Str.*) *flavohalterata* Bisch, the percentage incidence ranging from 2·5 to 52·5. The eggs are also occasionally attacked by *Trichogramma* sp.

I am grateful to Drs. M. Q. Khan, joint director of agriculture, Andhra Pradesh, and M. Puttarudriah, Government entomologist, Mysore Agriculture Department, India, for facilities and for guidance and encouragement given during the course of this work.

Age Determination of Seals

A WORD of warning is necessary when the number of cementum rings in the canine teeth of seals is used to determine the age of some species of Phocidae. As Mansfield and Fisher[1] have stated, they were able to count 18–20 rings in a tooth of a harbour seal (*P. vitulina* L.) of 19 years of age. For practical purposes this is good enough in the higher range of years, but the possible error becomes disproportionately large if applied to years 1–10; years which contain the critical years of sexual maturity both potential and actual.

Great care is needed in assessing the age of young seals, since the doubt inherent in the statement '18–20' is derived from real difficulties met with in counting the rings deposited in the earlier years of life, and in assessing the value of the 'last' ring.

Some years ago it became desirable to know the exact age of specimens of the grey seal (*Halichoerus grypus* Fab.). The rings in the dentine are not obvious, and in any event, as Laws[2] had shown, the teeth (canine as well as the others) rapidly become filled with dentine so that after the first few years no further deposition is possible. The rings of the cementum offered an alternative provided they were annual. Thanks to the kindness of Mr. Colin Matheson, of the National Museum of Wales, a longitudinal section was obtained in June 1956 of the canine tooth of a cow grey seal which died at the age of at least 26½ [3]. In this at least 25–26 rings could be counted, but the exact number was doubtful. However, the supposition that the rings were annual in origin was upheld. In November 1958 a cow grey seal, exactly six years old, died in the Zoological Gardens, Regent's Park, London, and a section of the canine tooth showed six clear and complete rings. Meanwhile, grey seals approximately 6½ months and 7½ months old had been obtained, marked on the Farne Islands in the previous November. These two showed clearly the deposition in part of the first annual ring of cementum. More recently, younger grey seals have been obtained which show that cementum is first deposited about 3–4 months after birth, somewhat unevenly in two bands on the root. These bands afterwards coalesce.

The primary cause of the difficulty in counting the rings is that the earlier ones are broad without sharply defined edges. The evidence so far suggests that these broader rings are deposited before sexual maturity. The fact that they are visible at all suggests that the semi-starvation during the moult is responsible. Thus the 'years' measured by cementum rings are 'years' following moult. If the moult is many months after the breeding period (birthday) it is possible to count only, say, five rings when the seal is in its sixth year of life. Thus the 'last' ring must be looked for very carefully and the degree of its deposition related to the period of moult, if known.

Sufficient material (118 specimens) has now been collected for the grey seal and a paper giving full details and relating age with sexual maturity is in preparation. Much of this work must be repeated if the technique is to be applied critically to other species of Phocidae.

Abnormal Crimping in Merino and Polwarth Wools

AN abnormal wool, more apparent on older sheep and known as 'doggy' wool, is a cause of considerable financial loss in some Merino and Polwarth flocks. Such wool is frequently lustrous and is characterized by reduced frequency of crimps, so that in extreme cases the fibres are almost straight and hair-like. Preliminary evidence is presented here that doggy wool is associated with hyperplasia and cyst formation of the outer root-sheaths of a considerable proportion of the follicle population of affected sheep.

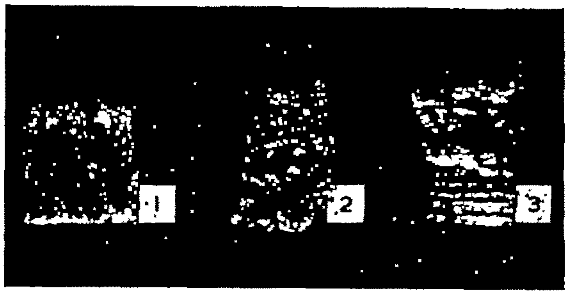

Fig. 1. Crimp deterioration in fine Merino and Polwarth wools in changing from normal (1) to 'doggy' (3)

In changing from normal to doggy, fine and medium Merino and Polwarth wools pass through an intermediate phase with secondary waves superimposed on the normal crimp; in strong Merino wool the change seems to be directly to a broader or irregular crimp. Fig. 1 illustrates the changes in fine Merino and Polwarth wools. The stages of crimp deterioration are somewhat similar to the changes produced in wool by a diet deficient in copper, but unlike the latter are not corrected by copper supplementation. The crimp aberrations are generally seen first in the loin, hip and thigh regions of the fleece, and the whole fleece may be affected within 1–2 years. The age at which the abnormality appears varies from 2 to 5 years in different strains of the Australian Merino, and the incidence also varies among the strains.

The main point of difference between normal and doggy wool is the changed crimp frequency. Routine examination of histological transverse sections of skin at the level of the sebaceous glands does not reveal any differences of significance. However, serial transverse and longitudinal sections of skin reveal grossly enlarged outer root-sheaths just above the bulbs of many follicles in the skin of sheep with crimp aberrations. Both primary and secondary follicles are involved, and in some follicles one or more localized enlargements form cysts, each of which is attached to the outer root-sheath by a narrow bridge of cells. Serial sections have established that these cysts are outgrowths from the outer root-sheaths. Fig. 2*a* shows a longitudinal section through a follicle with a cyst formed on an enlargement of the outer root-sheath, and Fig. 2*b* a transverse section of a number of follicles with outer root-sheath enlargements and cysts.

While occasional cystic sebaceous glands may be seen in the skin of sheep growing normal wool, particularly in aged sheep, the proportion of follicles with enlargements and cysts of the outer root-sheaths

Table 1. PERCENTAGES OF FOLLICLES SHOWING ABNORMALITIES IN MID-SIDE SKIN SAMPLES FROM SHEEP WITH DIFFERENT DEGREES OF CRIMP ABERRATION

Sheep	Crimping	Abnormal follicles (per cent)	
		With enlarged outer root-sheaths	With cysts
8- and 9-year old fine-wool Merinos	Normal	6	6
	Moderately doggy	34	7
	Very doggy	49	18
3 years old Polwarths	Well crimped	9	2
	Moderately irregular	25	8
	Very irregular	48	21

increased with severity of crimp deterioration (Table 1). Direct evidence of the association between enlargement of the outer root-sheath and reduction in crimping was obtained by plucking the straightest fibres from pieces of skin from sheep with different degrees of crimp aberration, and then sectioning the follicles longitudinally. In each instance of a follicle without a fibre there was enlargement of the outer-root-sheath either with or without cysts.

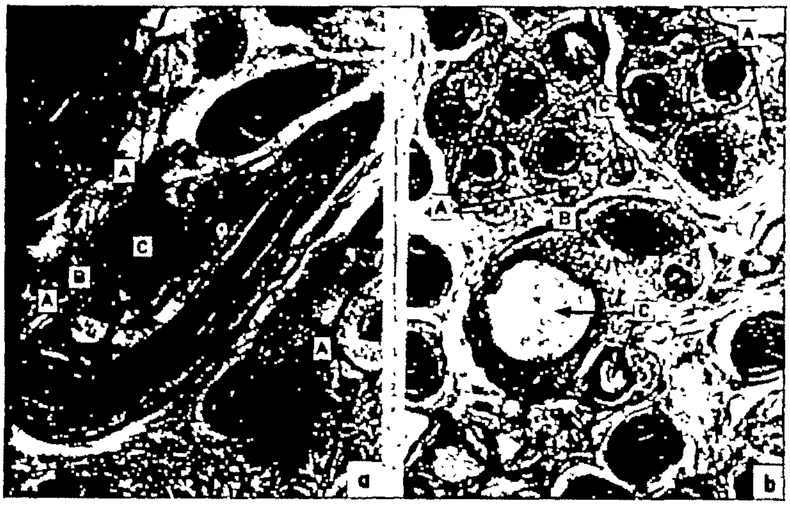

Fig. 1. *a*, A longitudinal section and *b* a transverse section through abnormal follicles showing enlargements of the outer root-sheaths (*A*) with cysts (*C*) attached by bridges of cells (*B*)

Although structures similar to these cysts have been described by others[1,2], to our knowledge the association between enlargement of the outer root-sheath and crimp deterioration has not been previously recorded. According to our evidence the outer root-sheath plays an important part in the process of fibre crimping. It may be, for example, that cyclic movement of the follicles is involved in the normal crimping of the fibres, and that these crimp irregularities are due to the added and variable resistance to movement of follicles with enlarged sheaths. The cysts could act as additional anchors, as they are frequently as large as the follicle bulbs and sometimes much larger. The observed proliferation of outer root-sheath cells is presumably accompanied by changed biochemical activity. This could conceivably alter the surface properties of the fibres, thus producing the lustrous appearance, and affect the process of crimping.

Abnormal crimping also occurs in fleeces of Corriedale sheep, and observations are being extended to this and other breeds. A detailed comparison is being made with the effects produced by a deficiency of copper in the diet, and this will be reported elsewhere.

Banana Fruit-spot ('Speckle') caused by *Deightoniella torulosa* (Syd.) Ell.

Deightoniella torulosa (Syd.) Ell. (syn. *Brachysporium torulosum* Syd.; *Cercospora musarum* Ashby; *Helminthosporium torulosum* (Syd.) Ashby) has been recorded on banana leaves and fruits in most major growing regions (Commonwealth Mycological Institute, Kew, Surrey, Distribution Map No. 175). The majority of earlier references to this fungus have concerned a leaf disease known as 'black-spot'[1-3] and a blackening of the tips of banana fruits[4,5].

A serious spotting of Lacatan bananas known in Jamaica as 'speckle' or 'swamp-spot' causes considerable wastage, particularly during rainy seasons. Fruit-spot may be observed in the field on fruit at all stages of maturity, the intensity of spotting increases with maturity being most noticeable at the time of harvest. In immature, green bananas, disease is first manifest as minute, reddish-brown spots each having a characteristic halo of dark green, apparently water-soaked tissue. As the spot increases in size, its outline remains circular, or nearly so. The largest spots observed so far had diameters of about 4 mm.: in these cases, the centre of the spot was dark brown or black and slightly depressed. The large proximal ('butt-end') hand of the bunch is usually more severely affected than the smaller, more distal ones. On each finger (that is, individual banana fruit), spots tend to be concentrated, on the outer face, towards the tip, and, on the inner face, towards the finger-stalk. There is evidence to suggest that the severity of spotting increases during ocean transportation and subsequent ripening of fruit.

External symptoms and anatomical details of the Jamaican fruit-spot are similar to those of a spot described by Johnston[6] and Johnston and Slocum[7] on Gros Michel bananas in Central and South America. These workers considered fruit-spot to be in the nature of a physiological disorder. Wardlaw[8] described several forms of spotting of bananas in Trinidad, but none of them would appear to be identical with Jamaican 'speckle'.

In the present investigation, *D. torulosa* was consistently isolated from spots of various diameters: no other fungus (or bacterium) appeared on the isolation plates. Pathogenicity tests were carried out in the laboratory and in the field by spraying the surface of apparently healthy fruit with a conidial suspension of *D. torulosa*. After 48 hr. under high humidity conditions, small but typical spots appeared on all inoculated fruit. Control fruit, sprayed with sterile water only, did not develop spots. *D. torulosa* was consistently re-isolated from artificially induced spots.

In a film of water on the surface of banana fruit peel, conidia of *D. torulosa* germinated after 1 hr.: after about 6 hr. one of, or both, the germ-tubes produce a swollen appressorium. Vertical microtome sections, 8–10μ thick and stained with 1 per cent cotton blue in lactophenol, showed that the appressorium soon produces an infection hypha which penetrates the cuticle and epidermal wall by mechanical means. This stage of infection was observed after 12–20 hr. After penetration has occurred, the epidermal cell becomes filled with a reddish-brown, granular substance. Further tissue invasion occurs by hyphal penetration of cell walls.

Similar stages in this infection process were observed on naturally infected fruit.

From the evidence outlined above it seems clear that *D. torulosa* is the organism causing fruit-spot of Jamaican Lacatan bananas. A detailed account of this work will be published elsewhere.

A Method for the Isolation of Plant Protoplasts and Vacuoles

The isolation of bacterial[1] and fungal protoplasts[2,3] following the use of enzymes digesting the cell wall suggested that protoplasts might be obtained from plant cells by treatment with cellulase. Root tips of tomato seedlings (*Lycopersicum esculentum* Mill. var. Sutton's 'Best of All') were selected for investigation, and a fungal cellulase obtained from *Myrothecium verrucaria*[4] (kindly supplied by Dr. D. R. Whitaker, National Research Council, Canada) was employed.

0·5-cm. root tips of tomato seedlings grown under aseptic conditions were treated at 27° C. with 5 per cent *Myrothecium* cellulase in 0·02 *M* phosphate buffer *p*H 6·0, containing 0·6 *M* sucrose as an osmotic stabilizer. Microscopic examination of the root tip, mounted under a cover slip, showed the formation of numerous spherical protoplasts after 2 hr. of treatment with cellulase. Two types of protoplast were identified. One type was unvacuolated (Fig. 1), and could be seen to be formed from the cells of the unvacuolated meristematic region of the root tip. The other type of protoplast was vacuolated with one or more vacuoles (Fig. 2) and was formed from vacuolated cells approximately 1 mm. from the root cap. Prior to their liberation these vacuolated protoplasts could be seen inside the remains of the partly digested cell walls, and it was evident that plasmolysis of cells by the hypertonic buffered sucrose was assisting in the ready isolation of intact vacuolated protoplasts.

These vacuolated protoplasts were stable in 0·3 *M* sucrose (0·02 *M* phosphate buffer, *p*H 6·0) for at least 6 hr. at 27° C. However, when suspended in 0·1 *M* sucrose (0·02 *M* phosphate buffer, *p*H 6·0) rapid lysis ensued with bursting of the plasmalemma and concomitant release of intact, yet swollen, vacuoles together with the protoplasmic contents. A typical group of such isolated vacuoles surrounded by their tonoplasts with adhering protoplasmic material is shown in Fig. 3. It was noteworthy that protoplasts were not formed from cells of the more differentiated region of the root tip bearing root hairs. The failure to isolate protoplasts from cells of this region was probably related to the different state of the cell wall[5] and to the presence of plasmodesmata linking the protoplasts of adjacent cells[6].

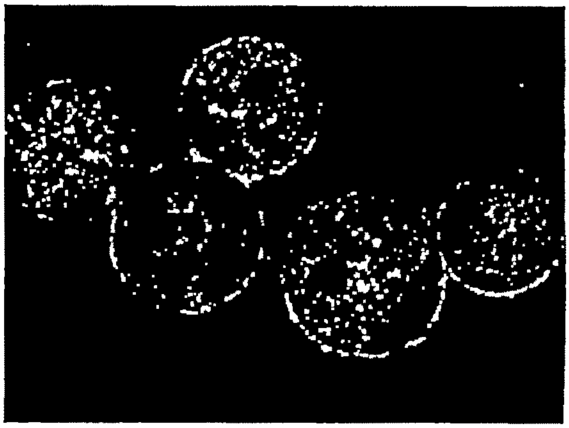

Fig. 1. Unvacuolated protoplasts (phase contrast)

It is clear that the vacuolated structures shown in Fig. 2 are protoplasts as defined on the basis of the criteria of Brenner *et al.*[7], since they are structures formed from that part of the cell which lies inside the cell wall and which can be plasmolysed away from the cell wall. In the case of the unvacuolated structures, shown in Fig. 1, it is more difficult to establish on the basis of similar criteria that these are in fact protoplasts, since they are formed from meristematic cells which are not readily plasmolysed[8] in which the cell wall is very intimately associated with the protoplasm[6]. Nevertheless, it was possible to observe various stages in the removal of the cell wall of these unvacuolated cells before attainment of the final

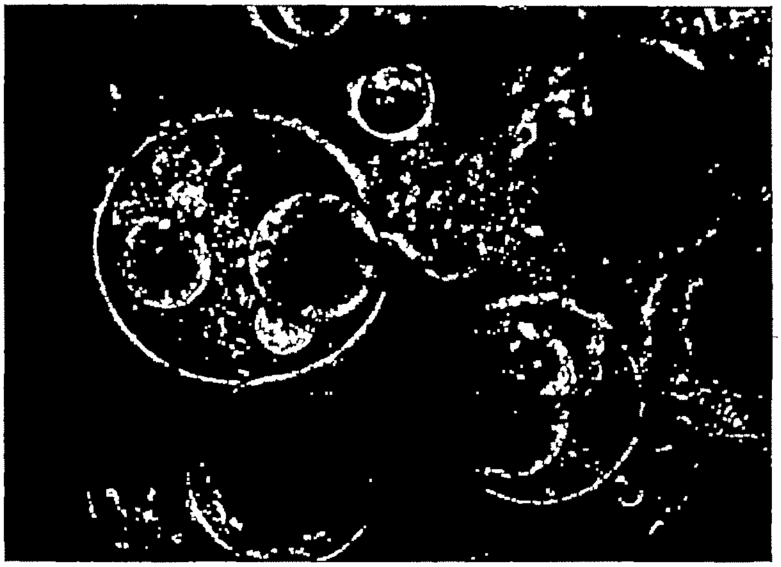

Fig. 2. Vacuolated protoplasts (phase contrast)

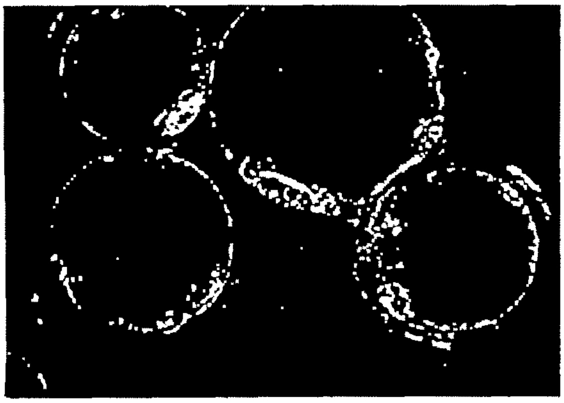

Fig 8. Vacuoles (phase contrast)

spherical form, both in cellulase-treated root tips and in cellulase-treated single unvacuolated cells isolated from root tips by the action of ethylenediamine tetraacetic acid[9].

ENTOMOLOGY

Bacteria as a Source of Food for Black-Fly Larvæ

Black-fly larvæ (Diptera : Simuliidae) are almost entirely confined to flowing water. They have long been known as 'filter-feeders', but the minimum particle-size acceptable as food by the several instars has not been previously investigated. Several authors have reported the occurrence of larvæ in sewage-contaminated waters ; but Petersen[1] was apparently the first to suggest that they might feed on suspended particles as small as bacteria.

This hypothesis is under investigation at Saskatoon in an attempt to determine some of the causes of destructive outbreaks of the black-fly, *Simulium arcticum* Mall. Larvæ of this species are sometimes excessively abundant in the north and south branches of the Saskatchewan River which originate in the Rocky Mountains of western Canada and discharge up to 140,000 c.f.s. into the confluence. During the spring and early summer, when these larvæ are most abundant, this river is generally in flood and the water very muddy with up to 1,000 p.p.m. of suspended solids. At the same time, macroplankton, the usual food of black-fly larvæ, are relatively scarce but bacteria are abundant. Species of bacteria present indicate an origin in sewage from the several cities situated on the river as well as from soil erosion.

In preliminary experiments at Saskatoon an attempt was made to rear first-instar larvæ of *S. vittatum* Zett. and *S. venustum* Say in sterile solutions of soluble nutrient in water flowing at 0·3–1·4 ft. per sec. In the absence of discrete particles these larvæ failed to develop beyond the second instar[2]. In similar, but non-sterile, solutions the larvæ developed to maturity, and adults were produced. Five species of bacteria, including three commonly found in soil and water, were isolated by Dr. G. Dempster, University of Saskatchewan, Saskatoon.

In further experiments 90 adults of these two species of black-flies were reared from 1,360 first-instar larvæ in distilled water containing only a washed suspension of *Bacillus subtilis* (Ehr.) Cohn, a normal component of soil. Fresh bacteria were added at 2- to 3-day intervals, keeping populations at about 160,000 viable bacteria per ml. of aquarium water. Microscopic examination showed that the bacteria were not clumped, and that most were present as single cells rather than in chains. About 65 per cent of the larvæ were lost in the first instar, possibly as a result of injuries received in handling. Rate of development was comparable to that in Nature : 21 days from hatching to the first pupa and a further 6 days to the first adult. These investigations are continuing and a detailed report will be published later.

Laboratory experiments have thus far been confined to larvæ of *S. vittatum* and *S. venustum* because of the difficulty in providing rapidly flowing water as in aquaria required by *S. arcticum*. However, the mouth-parts of these three species are very much alike, and thus similar results with the latter species may eventually be obtained.

The fact that all instars of larvæ of *S. vittatum* and *S. venustum* can obtain adequate nutriment from particles as small as *B. subtilis* is significant from two points of view : (1) Sewage bacteria entering a river may serve as food for black-fly larvæ. Thus the severity of black-fly outbreaks originating in rivers such as the Saskatchewan, Mississippi, Danube, Leine, Nile, etc., may be expected to increase as the amount of sewage entering them is increased. Reports[3,4] and personal observations indicate that livestock losses as a result of black-fly outbreaks along the Saskatchewan River have increased in the past 40 years. Enigk[5] reports that black-flies are appearing in larger numbers in Germany, and suggests that this is due to increased soiling of brooks and rivers. Losses adjacent to the Danube River appear to have been increasing during the past two hundred years[6]. (2) This suggests an unusual food-chain in the Saskatchewan River and perhaps other rivers which seasonally contain relatively little macroplankton but considerable bacteria and numerous filter-feeding black-fly larvæ. Fish, including *Moxostoma aureolum* (Le Sueur) and *Hiodon alosoides* Raf., containing black-fly larvæ were collected from the Saskatchewan River. Numerous larvæ-eating fish are known from the Danube[6].

Accessory Glands of Gené's Organ in Ticks

DURING dissection of gorged adult females of *Hyalomma excavatum*, *Rhipicephalus sanguineus* s.str. and *Boophilus annulatus*, we noted two hitherto undescribed groups of accessory glands, one on each side of Gené's organ.

The glands become evident soon after the onset of feeding and continue to develop during the period of digestion of the blood meal. In *Ripicephalus*, which oviposits 2–3 days after gorging, the development is completed during this interval; in *Hyalomma*, in which oviposition occurs ten days after gorging, the development is correspondingly slow. The glands attain full development by the time oviposition begins. They were not detected in the starved female or the nymph. We did not find these glands in adult *Ornithodorus tholozani*.

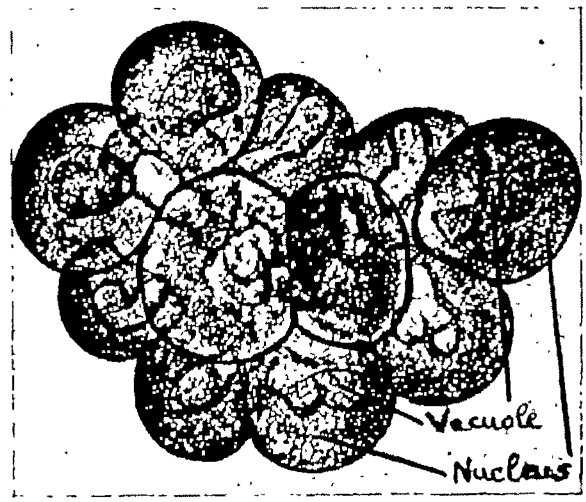

Fig. 1 New accessory gland from a female of *Rhipicephalus sanguineus* s.str., on the third day of oviposition. (× 140)

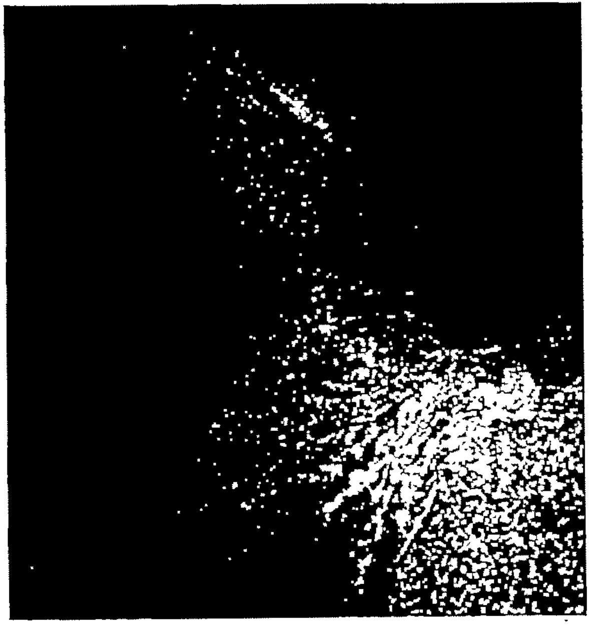

Fig. 2. Droplets of secretion on their way through the intracellular channel from a laying female of *Rhipicephalus sanguineus* s.str. (× 660)

Each group of glands consists of about 40 units in the case of *Hyalomma* and between 20 and 25 in the case of *Rhipicephalus*.

Each gland consists of about 10–13 cells. In general the cells are arranged roughly in a circle (Fig. 1). The large nucleus (up to 85μ) is situated in the lateral part of the cell; it contains several nucleoli. In each cell there is a large vacuole which grows continuously and attains a size of about 100–130μ at its maximum development. Each gland has a duct issuing from its centre; a narrow intra-cellular channel passes from each vacuole to the narrow main duct. On staining with methylene blue, droplets can be traced on their way from the vacuole via the narrow intra-cellular channel into the duct (Fig. 2).

These glands apparently contribute to the secretions of Gené's organ which protect the eggs in their external environment.

This investigation was supported by Research Grant No. 4531 from the National Institutes of Health, U.S. Public Health Service.

CYTOLOGY

Induced Fluorescence with Acridine Orange, after Osmium Fixation

THE differential staining of nucleic acids with fluorochromes[1] has provided a useful tool for the study of virus-infected tissue cells[2]; but its value has been limited by the fact that the common fixatives which permit the use of this method also tend to produce artefacts, such as the gross nuclear vesiculation observed in cells infected with some types of adenovirus[2], but not observed by phase-contrast examination of the living infected cell[3].

This serious limitation could be overcome if the technique could be adapted for use with fixation by osmium tetroxide, which has been shown to preserve faithfully most of the structural features of the living cell[4,5]. Up to the present, however, this has not proved possible, and reports indicate practically no affinity between the diamino-acridines and nucleic acids fixed in osmium tetroxide[3].

Recent work in this laboratory has shown that this lack of affinity may be overcome if staining is carried out with acridine orange in alcoholic solution, in place of the buffered aqueous solution, as usually practised. The technique described is simple and uniformly successful, giving vivid colour differentiation and even staining over the entire preparation. Acridine orange *R* (2,8-*bis*-dimethylamino-5-phenylacridine hydrochloride, Colour Index No. 792) in 1 : 1,000 dilution in industrial methylated spirit ('Methool') was used, and this was filtered before use. The end result was found to be the same, however, using dilutions of lesser or greater strength, and allowing for an appropriate alteration in the staining time.

Cells of the 'ERK' cell line[6] were grown on glass microscope slides to form a near-confluent monolayer. The medium was washed off with phosphate-buffered saline, *p*H 7·2, and sample slides were then fixed either in the vapour from 1 per cent osmium tetroxide for 10 min., or in the buffered osmium tetroxide solution of Palade[5] for the same length of time. Both sets of cultures were thoroughly washed in several changes of distilled water, during half an hour, and this was followed by a brief rinse in 'Methool'. They were then transferred to a covered staining jar containing the alcoholic solution of acridine orange, and stained for 10 min. On removal, the slides were thoroughly washed in phosphate buffer made up of potassium dihydrogen phosphate 4·5 gm., ammonium chloride 0·5 gm., ammonium sulphate 0·5 gm., per litre adjusted to pH 7·6 with sodium hydroxide and finally mounted in liquid paraffin.

Examination was carried out with a simple system using a projector lamp of the solid-source filament type, an Abbé type condenser, a cupro-ammonium cell of suitable density, and a yellow eye-piece filter. An alternative system, using a high-discharge mercury vapour lamp, dark ground condenser, and appropriate filters, did not materially improve the picture obtained.

Both methods of fixation gave equally good results, with sharp differentiation of the cellular elements corresponding to the nucleic acid pattern. The nucleoplasm of interphasic cells appeared homogeneous, fluorescing as a clear, bright greenish-yellow. Nucleoli showed prominently as discrete, red bodies with their surrounding zone of 'associated' deoxyribonucleic acid seen as a halo of more brightly fluorescing yellow. The ribonucleic acid of the cytoplasm was uniformly intense, deep red. In dividing cells, mitoses were distinctive by their brilliant golden fluorescence and sharp configuration.

Semi-permanent preparations of this type, allowed to remain on the bench at room temperature for at least a month after sealing, have shown no deterioration. Liquid paraffin was chosen as the mountant, in preference to either glycerine, or glycerine–saline, since the fluorochrome is apparently unaffected by it, and no extraction of the dye occurs even after prolonged contact. Finally, it is a simple matter to renew bleached preparations, by removing the liquid paraffin with washes of alcohol and then repeating the treatment with alcoholic acridine orange.

A Polyploidizing Principle in the Spleen

IN previous experiments it has been found that 120 hr. after traumatization of the uterus the number of large homogeneous cells in the antimesometrial part of the deciduomata was doubled in splenectomized rats[1]. In other experiments the animals were partially omentectomized or unilaterally nephrectomized. But there was no difference in cell count between these animals and the non-splenectomized controls[2]. The proportion of the volume of the nuclei of the large decidua cells between normal rats and spleenless ones[3] was approximately 2 : 1. The number of countable nucleoli in each nucleus shows the same ratio[4].

These changes, appearing after the extirpation of the spleen, can be prevented by saline extracts of the spleen from rat, cattle and horse. Further, it has been shown that a linear relation exists between the logarithms of the quantity of injected saline extract and the number of large decidua cell nuclei. From these experiments one may conclude that the discernible changes in the nuclei after splenectomy were dependent on changes of the degree of ploidy. Therefore a substance producing a polyploidizing effect was supposed to exist in the spleen[1]. The direct evidence of that polyploidizing effect was obtained by counting the chromosomes.

With female inbred rats of an average body-weight of 200 gm. a pseudo-pregnancy was induced by sterile copulation. 'Spirocid' (167 mgm./kgm. body-weight/day) was then given orally for three days to prevent the manifestation of a latent infection with *Bartonella muris ratti* after splenectomy. 96 hr. after the sterile copulation the animals were operated under ether anæsthesia: both horns of the uterus were traumatized by making several stitches through the lumina. In six animals the spleens were removed in addition; in three animals serving as controls parts of the omentum were excised. The splenectomized animals were divided into two groups. One group remained untreated. The other group was subcutaneously injected with saline extract of cattle spleen immediately after the operation and for the following four days. 120 hr. after operation all animals received 0·2 mgm./100 gm. body-weight colchicine intracardially and were killed by carbon monoxide 2 hr. later. Then the

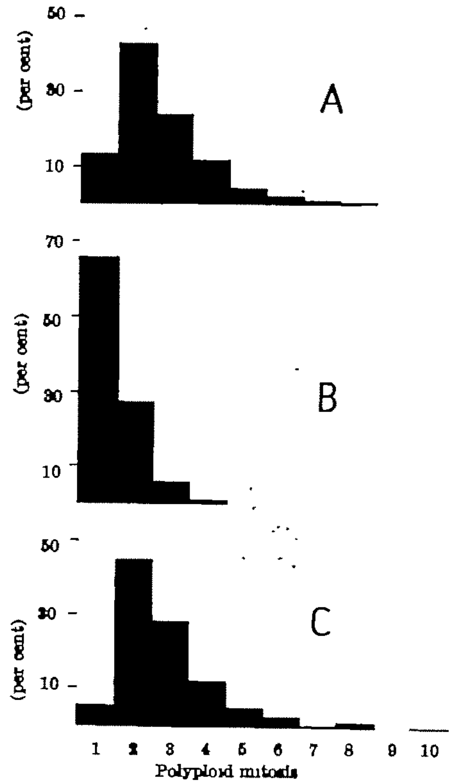

Fig. 1. Three histograms demonstrating the distribution of the degree of ploidy in metaphase plates of the large decidua cells. Each histogram is based on 500 mitoses of three rats. *A*, omentectomized rats; *B*, splenectomized rats; *C*, splenectomized rats which received saline extract of cattle spleens

uteri were prepared, the myometrium was dissected and the antimesometrial decidua was cut out. After removing the adhering blood the tissue was cut into small pieces which were suspended in 0·00075 *M* 8-oxychinoline solution for 1 hr. The tissue was then fixed for 3 hr. in ethanol–acetic acid, 3 : 1, and afterwards preserved in 70 per cent ethanol. For further preparation these pieces of tissue were stained for 30 min. in carmine–acetic acid containing 10 per cent glycerol[5]. Then they were picked with needles into tiny pieces and squashed under a cover-glass. The chromosomes were counted by means of a phase-contrast microscope at 2,000- or 3,000-fold magnification. Only metaphase plates were examined. Each mitosis was counted independently by two persons. In each group the chromosomes in 500 mitoses were counted. The numbers we found were classified as to the degree of ploidy. The haploid set of chromosomes was: $n = 21$. The limits of these degrees of ploidy were fixed as: $n \pm 10$, $2n \pm 10$, $3n \pm 10$ . . . . In total, 1,500 metaphases were counted in the antimesometrial part of the rat deciduomata. The results of these counts are demonstrated in Fig. 1.

From this it may be concluded that in the spleen there exists a polyploidizing substance, the chemical nature of which is not yet known.

SOIL SCIENCE

C Horizon of the Soil Profile

In the course of recent investigations on the pedology of fluvial soils located in the area of Durham City, no true *C* horizon could be observed in the numerous profiles and sections examined. In the case of so-called transported soils, it is, of course, well known that the *D* horizon will usually be unrelated to the solum. But the finding that the *C* horizon is absent in some of these soils is of pedological importance, and, so far as we are aware, has not previously been reported for soils of the United Kingdom. Nevertheless, the occurrence of soil profiles of this type would seem to be of more than local significance and may well be widespread.

The area under study formed part of the floor of a large glacial lake, which came into existence towards the end of the Pleistocene epoch, when varying thicknesses of fluvioglacial deposits were laid down. These deposits, which are often lenticular, are both heterogeneous and variable, particularly in texture, structure, colour, depth and drainage; they show clear evidence of water-sorting in the morphology of the profiles and sections.

The alluvial soils studied are located in an old flood plain of the River Wear and thus represent the results of the resorting and deposition by the action of water on the glacial and fluvioglacial deposits left after the retreat of the ice. They are therefore of similar mineral content to the local fluvioglacial deposits. These deposits are also extremely heterogeneous.

In general, the study of the profiles and sections of both fluvioglacial and alluvial soils revealed two distinct horizons—a zone of eluviation and a zone of illuviation; but it was not possible to distinguish a true *C* horizon although the investigation extended to Carboniferous age bedrock (shale) encountered between 19 and 24 ft. The *C* horizon is by definition the unconsolidated parent material substantially similar to that from which the solum has developed. Before such a horizon can be identified there must be evidence of this similarity, and this is not apparent in the profiles and sections studied. In these soils the parent material of the upper layer of the soil profile has been completely transformed into the *A* horizon. Probably it was different from the parent material of the *B* horizon and was not necessarily identical with any mineral material that can now be observed in the regolith. The relationship between the different soil horizons is dependent on pedological processes acting on parent material horizontally bedded and initially heterogeneous. The horizons below the zone of illuviation must be regarded as *D* horizons, because any unconsolidated material beneath the solum not characterized as parent material is so designated[1]. In these soils the succession of horizons is therefore *A,B,D*.

It will be seen that the absence of a *C* horizon is, in effect, the result of one or more relatively thin layers of transported material originally constituting the upper zone of the deposits. A parallel case of interest has been recorded in the United States in regard to certain deposits of loess only 30 in. deep[2]. It is known that the *C* horizon may also be absent in the profile of soils developed *in situ* where the parent material is sufficiently resistant to weathering to result in the rate of formation of the solum keeping pace with the rate of rock weathering.

A further relevant experience has recently been encountered in an investigation of types of rendzina profiles developed on the magnesian limestone of Co. Durham: Glacial till was found to overlie the bedrock in some of the profiles studied. In cases where the layer of till was thin the typical rendzina profile was developed, but the *A* horizon has been formed from varying proportions of both till and the residues remaining from the weathering of magnesian limestone. In many cases the effective contribution of till is sufficiently great to preclude the underlying weathering magnesian limestone from being classified as parent material. In the case of these soils, the succession of horizons is therefore *A,D*.

It is hoped shortly to present elsewhere detailed reports of all these investigations.

Effect of Surface Density of Charge on the Physical Swelling of Lithium Montmorillonite

THE crystalline swelling of lithium montmorillonite before and after heating has been investigated by several workers[1–3]. Hofmann and Klemen[1] suggested that, on heating, the small lithium ion migrated into the crystal lattice to occupy a vacant octahedral site with consequent neutralization of the charge originating in that layer due to the isomorphous replacement of Al^{3+} by Mg^{2+}. They termed this 'place exchange'. This process gives rise to marked reduction in crystalline swelling.

Greene-Kelly[3] has followed by an X-ray technique the loss in glycerol adsorption for Li^{+} saturated minerals over the range of composition from montmorillonite to beidellite. For less than 70 per cent octahedral substitution he has found some penetration of glycerol. Complete penetration was obtained at about 10 per cent octahedral substitution. In other experiments he studied the effect of only partly saturating the exchange complex of montmorillonite with lithium; the other ions balancing the negative charge were normal in their behaviour after dehydration. At about 44 per cent saturation with lithium complete penetration of glycerol was observed, but for 68 per cent saturation with lithium only about one quarter of the internal surface was accessible to glycerol.

Recently, Johns and Tettenhorst[4] have demonstrated that the order of penetration into dehydrated crystals is ethylene glycol > glycerol > water. It was thought that a study of the physical swelling of Wyoming bentonite containing varying proportions of lithium and sodium might give useful information on the minimum surface density of charge required for large intracrystalline expansion.

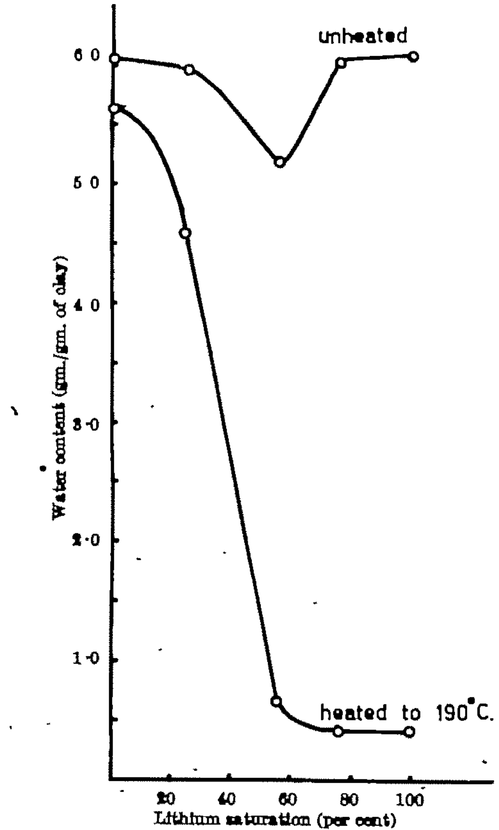

Fig. 1. Effect of percentage lithium saturation and heating on the water content of clay cores at 100 cm. of water suction

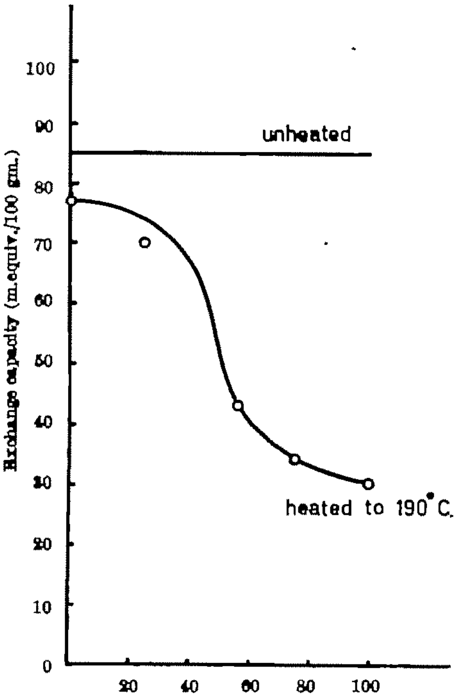

Fig. 2. Effect of percentage lithium saturation and heating on the exchange capacity of montmorillonite

Compressed cores of the clays were manufactured[5,6] from the control and heated clay powders. These cores were allowed to swell slowly to equilibrium with a hydrostatic suction of 100 cm. of water. The wetting liquid was distilled water and the results plotted in Fig. 1 reveal that at 56 per cent lithium saturation the clay has lost its capacity for large intracrystalline swelling as the control water content is greater than 5 c.c./gm. and the heated clay has a water content of 0·62 c.c./gm. This latter result can be compared with that for sodium montmorillonite in the presence of *M* sodium chloride when the solution content was found to be 0·90 c.c./gm.; for these circumstances the intracrystalline spaces of sodium montmorillonite do not expand beyond a basal spacing of 19 Å. (ref. 7). The lower water content (0·62 c.c./gm.) for the heated montmorillonite indicates considerable but not complete loss of internal surface. The water content for 75 and 100 per cent lithium saturation is a little more than 0·4 c.c./gm. This water content indicates limited swelling between crystals since the initial porosity of the clay core was 0·11 c.c./gm.

In Fig. 2 the exchange capacity of the clay samples, used in the swelling work, is plotted against lithium percentage prior to heating. The exchange capacities determined by the method used by Greene-Kelly and by strontium saturating were in good agreement; the strontium content of the clay was determined by an X-ray spectrographic method. The exchange capacity (0·80 m.equiv./gm.) for the lithium-saturated clay was much higher than reported earlier. This exchange capacity decreased to 0·20 m.equiv./gm. when the clay was heated to 300° C. These values for the exchange capacity appear to be too large to be accounted for by exchange on the external surfaces of the crystals since the crystals would have a surface area in the region of 50 m.^{2}/gm.

It appears that about 75 per cent saturation with lithium and heating to 190° C. are able to prevent crystalline expansion. At 56 per cent lithium saturation there is some penetration into intracrystalline spaces but large crystalline swelling is not observed. At 25 per cent lithium saturation, montmorillonite exhibits large physical swelling as the result of expansion beyond a potential barrier at a silicate sheet separation of 19 Å.

It can be concluded that large crystalline swelling is not obtained at a surface density of charge of about $0{\cdot}6 \times 10^{-7}$ m.equiv./cm.^{2}, but it is obtained at a surface density of charge of 1×10^{-7} m.equiv./cm.^{2}.

We are indebted to Dr. K. Norrish for the determination of strontium.

MATHEMATICS

Theory of Optimal Games

THEORY of games, and also theory of fair games, are well-known subjects, but a theory of good (or optimal) games does not seem to exist.

To theory of optimal games there would, for example, belong the question: Why, among serious poker-players, is it accepted as 'better' to play the game with a full pack and a hand of five cards rather than with, say, two Piquet packs shuffled together and a hand of seven cards? (The historical reason for this acceptance is not known, for the origin of poker is as obscure as is that of its name.)

That a game may possess different states of goodness is well seen from the varieties of two-handed whist. These may be epitomized thus: n full packs are shuffled together and equally divided among the two players; of the $26n$ cards that each player receives, kp are dealt face down to form k packets of p cards each; k are dealt face up, one on top of each packet, and the remaining $26n - k(p + 1)$ cards form the player's hand, from which, before the trump is declared, he must throw away r cards face down. When one of the k top cards is played, the card underneath it is turned up; and so on. In these games, obvious examples of zero goodness are (for all n), first, $k = r = 0$, and, secondly, $p = r = 0$, $k = 26n$; whereas, empirically, $n = 2$, $p = 3$, $k = r = 8$ 'makes rather a good game'.

In the context of theory of optimal games, it may be that croquet should receive consideration, for, in its (fairly short) history, it has, more than once, been felt non-optimal, and its controllers have altered the rules fundamentally (the most traumatic alterations being, perhaps, the decisions, first, to abandon play by rotation of colour, secondly, to award an optional lift against a player who is 'doing too well').

There would arise also the question: How far is competition a prerequisite of goodness? In patience games, this element is, naturally, lacking, yet many of the games are clearly 'very good', most notably, perhaps, those of the *Miss Milligan* series (of which Miss Milligan itself is, by trial and error, the optimal member). Croquet is a competitive game: the player of black-and-blue achieves success if he 'goes round' before the player of red-and-yellow; but there seems no reason why a 'croquet-patience', in which the two players combine to get all four balls round in as few turns as possible, should not be an equally good game.

Clearly, the great difficulty in theory of optimal games will be the establishment of a criterion, or measure, of goodness, and it may be that this establishment will not fall within the domain of mathematics; but, once a measure has been established, some mathematical analysis or, at least, a mathematical envisagement, of the problem might well be possible.

ALAN S. C. ROSS

University of Birmingham.

A Remark on Stochastic Path Integrals

VARIOUS stochastic functionals of the type:

$$S(t) = \int_0^t V(X(u), u)\, du \qquad (1)$$

where $X(u)$ is a stochastic process, have been studied in recent years (see, for example, Kac[1]). It seems worth noting that for $X(u)$ Markovian, there is often no particular difficulty in setting up characteristic function equations, of the type derived in my book[2] on stochastic processes (see especially the end of chapter 3), applicable not only to (1) but also to rather more general types of integral. Thus for:

$$S(t) = \lim_{\Delta u \to 0} \sum_{u=0}^{t} v(X(u), u, \Delta X(u), \Delta u) \qquad (2)$$

provided

$$E\,[\{\exp(i\theta\Delta S + i\varphi\Delta X) - 1\}|\, X(t) = x] = \Psi_S\,(i\varphi, i\theta, t, x)\Delta t + o(\Delta t)$$

we may set up an operator equation of the form:

$$\frac{\partial C}{\partial t} = \Psi_S\,(i\varphi, i\theta, t, \frac{\partial}{\partial i\varphi})\, C \qquad (3)$$

where $C \equiv E\,\{\exp(i\theta S(t) + i\varphi\, X(t)\,)\,\}$. A particular case given on page 86 of my book is $v \equiv X(u)\Delta u$. As further examples, consider $v \equiv [\Delta X(u)\,]^2$, for (i) the normal linear Markov process (which includes 'Brownian motion' as a special case) and (ii) the simple birth-and-death process, for which $S(t)$ records the total number of transitions. For (i), $S(t)$ then increases regularly with t (as is well known); for (ii), C is readily evaluated, either by (3) or even more easily from the corresponding 'backward' equation. A further amplification of these points will be given elsewhere.

FORTHCOMING EVENTS

Monday, September 12

Bone and Tooth Society (at 234 Great Portland Street, London, W.1), at 4.30 p.m.—Scientific Papers.

Saturday, September 17

British Interplanetary Society (in the Tudor Room, Caxton Hall, London, S.W.1), at 6 p.m.—Mr. P. A. E. Stewart: "A Programme for the Surface Exploration of the Moon".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Botanist or Biochemist, Scientific Officer grade (with an interest in field work), to grow and test plants for suitability as sources of protein—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (September 20).

Lecturer (with a particular interest in industrial organization or in advanced economic theory) in Economics—The Registrar, King's College, Newcastle upon Tyne 1 (September 24).

Senior Lecturer in Surgery—The Registrar, The University, Sheffield (September 30).

Lecturer (with special qualifications or interests in cytogenetics or experimental taxonomy) in Botany in St. Salvator's College—The Joint Clerk to the University Court, College Gate, St. Andrews (October 1).

Lecturer (with an honours degree, and preferably with a higher degree in chemistry with postgraduate experience of academic or industrial research) in Physical Chemistry—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3 (October 1).

Assistant Lecturer (with special qualifications in physical chemistry) in Chemistry—The Registrar, The University, Manchester 13 (October 15).

Lecturer (with an honours degree in psychology and some knowledge of statistical methods) in Psychology in the Department of Education—The Secretary, Cambridge University Department of Education, 17 Brookside, Cambridge (November 3).

Assistant Lecturer in Physics—The Registrar, The University, Nottingham.

Biochemist or Chemist (preferably with some experience in protein or enzyme work or in the natural product field), for work of a fundamental nature on the chemistry and biochemistry of plant proteins—The Director, Arthur D. Little Research Institute, Inveresk, Midlothian, Scotland.

Entomologist (with a good honours degree in zoology or entomology, preferably with postgraduate research experience in forest or timber entomology) at the West African Timber Borer Research Unit, Kumasi, Ghana, to undertake studies of the biology, ecology and control of timber and lumber pests—Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.197/510/01/01.

Fisheries Research Officer, Senior Scientific Officer or Scientific Officer grade (with a good honours degree in zoology and at least two years suitable postgraduate research experience or training) with the East African Fisheries Research Organization, Jinja, Uganda, for research on ecology and fish physiology—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.195/194/02/01.

Geologists (with a first- or good second-class honours degree in geology with emphasis on metamorphic and igneous rocks and/or structural geology, some previous experience is desirable), for duties in Tanganyika including the regional geological survey of metamorphic and igneous rock terrains and preliminary investigation of mineral deposits—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.105/8/03/T.

Hydrologists (with a university degree in civil engineering and preferably with a postgraduate diploma in hydrology, with at least two years relevant experience; consideration would also be given to candidates with a degree in applied science with some direct experience in applied hydrology) with the Ministry of Works, Kenya, for duties including the measuring of river flows, assessment of flood discharges, rainfall run off studies and assessment of groundwater resources, with recharge and depletion—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.112/7/01/T.

Lecturer or Junior Lecturer in the Department of Zoology and Comparative Anatomy, to participate in the teaching of medical and postgraduate students and with good opportunity to undertake research work—The Secretary, St. Bartholomew's Hospital Medical College, West Smithfield, London, E.C.1.

Plant Pathologist (with a good honours degree in a biological science and postgraduate experience in research or advisory work in plant pathology) in Tanganyika, for research and specialist advisory services in plant pathology—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/8/06/T.

Research Assistant, for chemical and radiochemical analytical work on minerals—Dr. J. R. Butler, Geology Department, Imperial College of Science and Technology, London, S.W.7.

Research Assistant (with an honours degree in physiology, physics or a biological subject), to assist in teaching and for experimental research in human lung function—Finance Officer, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1.

Research Assistants (honours graduates in physics), for work on problems concerned with counting techniques and high energy physics, gas discharges, spectroscopy or electronics—The Clerk to the Governors, Northern Polytechnic, Holloway Road, London, N.7.

Research Associate in Chemistry, for work on the physical chemical properties and syntheses of heteropoly compounds—Prof. Egon Matijevic, Department of Chemistry, Clarkson College of Technology, Potsdam, New York, U.S.A.

Research Fellow (with qualifications in biochemistry), for work with Dr. P. T. Grant on the enzymic aspects of oxidase systems present in mammalian trypanosomes—The Secretary, University of Aberdeen, Marischal College, Aberdeen.

Senior Scientific Officer or Scientific Officer (with a first- or good second-class honours degree in zoology, and preferably some evidence of aptitude for original research) with the East African Trypanosomiasis Research Organization, Tororo, Uganda, for work on the ecology of Glossina populations with special reference to sampling methods and to the factors determining population density and their relationship to modern methods—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.195/198/013.

Lecturer/Senior Lecturer (with at least an honours degree in mathematics, or equivalent qualification, and preferably with some research experience) in the School of Mathematics, University of New South Wales, to lecture and undertake research in the field of pure mathematics and preferably in the field of modern algebra—The Agent General for New South Wales, 56–57 Strand, London, W.C.2 (October 7).

SUPPORT FOR UNDER-DEVELOPED COUNTRIES

ONE of the most interesting, and possibly most significant, features of the annual report of the Colonial Development Corporation for 1959* is the stress laid on man-power. Some reference is made to this question in three sections of the general review of the year, although in that dealing with public relations no more is said than that a well-informed and interested staff are needed in the Corporation's work and that all staff at home and overseas are helped to realize that, while concentrating on their own particular work, they are contributing a significant part to a widespread and many-sided enterprise. The references made under management and under training schemes are of much wider significance, and illustrate the importance of much that Mr. Kenneth Younger urged in his Sydney Bull Lecture last November on "Trained Man-power for New States: the Scope for International Action", and in his subsequent study in some problems of trained man-power published under the title "The Public Service in New States"†. It might be added that Dr. E. B. J. Portman, rector of the Netherlands College for Representation Overseas, described the Dutch experiment in training staff for foreign posts to the Royal Society of Arts last January.

With enterprise so diverse in character and so widespread in location as that of the Colonial Development Corporation, it is impossible to over-stress the importance of efficient management, and in this latest annual report it is urged that such an organization can only be successful when there is full confidence in the reliability and competence of local management. The Corporation constantly gives special attention to this problem both in the selection of managers for those projects controlled directly or through subsidiary companies, and by making satisfactory expert management a necessary condition for financial participation in any development enterprise. As a result of the continued emphasis given to this aspect, the Corporation has accumulated much experience in judging the best form of management for many different kinds of undertakings, and has also built up a considerable team of trusted managers.

This management and the continued recruitment of suitable young people will only continue to be possible, however, if there is general confidence that the Colonial Development Corporation will be given the chance to grow, and if it is not constantly threatened with a contraction in its scope. Here, moreover, there are two aspects of the problem—organization and training—and both alike can affect recruitment. On the first, the report comments that important as is the selection of good management in the first instance, the process of watching the progress of that management and making changes where necessary is even more important, and it claims that the Corporation's methods of supervision through its regional organization are especially useful.

There can be no doubt from much independent criticism of technical assistance schemes that management has frequently proved one of the weakest points. This may have been due on occasion to bad selection, but more generally it is due to the lack of suitable managers or to imperfections of training. The Colonial Development Corporation is convinced that successful development of under-developed territories requires more than finance; capital investment must be guided and controlled by skilled and experienced management, and it is particularly important that development should proceed as a partnership with the local people in each country.

Through its regional organizations, subsidiary companies and projects, the Corporation is helping suitable people in British overseas territories to undergo business training to equip them to hold responsible posts in any commercial organization. Several candidates from Nigeria, Malaya and the West Indies have already received training in management in the regional and London offices of the Corporation, and scholarships at Commonwealth universities are now being offered in the West Indies and in North Borneo. Training for technical and supervisory positions is being given on projects in the West Indies, the Far East and in various parts of Africa.

In this field, therefore, the Corporation is making a contribution to educational co-operation in the Commonwealth that is by no means negligible, and which underlines both the urgency and the importance of the task of education in the dependent and newly independent territories alike. Mr. Younger's lecture, and even more his book, help to put it in a wider perspective. Both the lecture and the book are concerned primarily with the new States, and accordingly with a field where the Colonial Development Corporation, for example, does not operate. Apart, however, from the fact that these States, most of which are former Colonial dependencies, face many of the same problems as all under-developed territories, the newly independent States have usually a fairly extensive trained administration, consisting largely of expatriates, and their national life and economy are geared to the existence of this corps of trained administrators, many if not most of whom are likely to leave, at or soon after, independence.

These trained administrators cannot be replaced immediately, and Mr. Younger is not concerned simply with the problem of educating and training the people of these States to fulfil such positions, or with the special problem of maintaining relatively modern and sophisticated services during a vital transitional period before such indigenous trained man-power is adequate. He is equally concerned, more especially in his book, with what could be done before independence is reached to ease this transitional period. Moreover, while the major burden of creating a supply of trained man-power must inevitably fall on the new States themselves, which cannot escape the long process of building up a population generally educated for the needs of a modern society, Mr. Younger points out that the process can be accelerated by the conscious adoption of certain priorities in education and training, and that substantial assistance can be given from outside.

---

* Colonial Development Corporation. Annual Report and Statement of Accounts for year to 31.12.59. Pp. v+77. (London: H.M. Stationery Office, 1960.) 5s. net.

† The Public Service in New States: a Study in Some Trained Manpower Problems. By Kenneth Younger. Pp. viii+113. (London: Oxford University Press, 1960.) 12s. 6d. net.

This, Mr. Younger believes, should be one of Britain's main pre-occupations with her overseas territories, and it is of course one of the main purposes both of the Commonwealth Scholarship and Fellowship Plan and of the other measures of Commonwealth educational co-operation resulting from the Commonwealth Education Conference. Like Dr. B. V. Bowden, of Manchester, he points out that even where there is a substantial element of trained man-power, as in Ghana, it is ill-balanced ; and while there may be a full or excessive complement of lawyers alongside a desperate shortage of scientists and engineers, even the existing supply of the latter may be ineffectively used for lack of sufficient technicians or craftsmen. Little has been done until recently to correct the tendency of young scholars in such territories to prefer the arts to science ; but the measures resulting from the Commonwealth Education Conference offer a much better opportunity of correcting their preference by planning higher studies and overseas scholarship programmes with the view of meeting the most pressing needs of particular territories.

Discussing more particularly this transitional period, Mr. Younger points out that while the extent to which expatriate long-service administrative officers and professional and technical officials have been replaced by locally recruited men in the independent territories varies from one territory to another, it rarely much exceeds 50 per cent and is frequently much less in the senior grades. The ideal solution in such circumstances is a phased run-down of the old service, as locally recruited men become available, and this may take anything from three to fifteen years. The process has been successfully worked in the Federation of Malaya and was not unsuccessful in Ghana, while the prospects for Nigeria are reasonable. Success is only possible in favourable political circumstances. In Indonesia, the Sudan and Guinea, for example, a sound relation between the new Government and the old Colonial Service was unattainable for political reasons, and sources of man-power had to be sought apart from the former Colonial power.

No international organization yet exists on a scale which would enable it to step in and make good major deficiencies in trained man-power in an emergency, and Mr. Younger in his lecture suggests that such situations could be far more advantageously handled if international organizations were suitably expanded and strengthened. Once this transition is past, new States are on the same footing as all other underdeveloped territories and have to build up education at all levels, increasingly in their own countries, and with their own teachers. Mr. Younger stresses this indigenous aspect strongly. While he emphasizes that Britain deserves much credit for creating the existing institutions of higher education in Africa, he points out that these are only a small nucleus of what is required, and he has formed the impression that the Governments of highly developed nations, for example, the United States, Britain and France, find it easier to provide scholarships in their own institutions than to give help in developing local institutions.

Whether this is true or not—and it could in part be a consequence of the shortage of trained man-power, especially of scientists and technologists in these countries—the United Nations Technical Assistance Administration has undoubtedly found, in the promotion of training facilities on the spot in various areas, a field which has been neglected by others. Considering the relatively small scale of United Nations activity which Member States have so far been willing to finance, Mr. Younger thinks the United Nations can claim to be making an outstanding contribution in this limited field, although its current annual budget for the Expanded Programme of Technical Assistance is only just over 33 million dollars, supported, however, by substantial counterpart funds in local currency from recipient Governments. Further, successful projects tend to set in motion activities eventually out of all proportion to the initial cost. Some 86 countries have contributed to the programme, and 140 territories have benefited from it : in 1958 experts were drawn from 64 different countries and senior men were sent for training to 68. The experts are mostly international officials, paid by and answerable to the United Nations, and the service has been fairly stable in size for several years. It differs from the more recent Operational and Executive Service of the United Nations, now known officially as Opex, put into operation in 1959 with a maximum of 25 officials, who go out as employees of the Government requesting assistance.

Mr. Younger does not foresee a spectacular growth of this service on the purely administrative side, but on the professional and technical side it might grow considerably and the demand remain steady almost indefinitely. He suggests, therefore, that it should be given some relative permanence, so that it could hope to include a proportion of men who make international overseas service their career and consequently become genuinely expert in its techniques. It would, he suggests, be little if at all easier for Britain than for the United Nations to provide a constant stream of first-class professional and technical men on contract, which is the main requirement to-day. In West Africa, for example, an international body which could build up a corps of experts familiar with the problems of the whole area and capable of transcending the artificial boundaries dividing the former British and French Colonies would have a real advantage. To treat West African medical, agricultural and forestry problems as a single whole would economize in man-power and serve as a useful antidote to 'Balkanization', which is one danger threatening the area after the end of Colonial rule.

It is in this context and that of the proved success of the United Nations in setting up institutes and schools of public administration in South and Central America and in helping to create similar establishments in Egypt, Ethiopia, the Sudan and Turkey, and providing skilled help and advice in this field in other countries of Asia and Africa, that Mr. Younger raises the question whether the Member States of the organization are now willing to turn technical assistance into a major force in world development or not. He thinks that new States would welcome an increase in multilateral aid, but they cannot be expected to press for it so long as it is evident that those Powers, which have both capital and skilled man-power to contribute, are unwilling to supply through international channels more than a fraction of the assistance they offer on a national basis. Nevertheless, he suggests that in the matter of trained man-power, the long-sighted policy would be deliberately to build up international services, both world-wide and regional, as the instruments best suited to future needs, and to the conditions of the post-Colonial period.

Mr. Younger's book describes a study undertaken at the request of Nuffield College, Oxford, and the Leverhulme Trust and based on a visit to Ghana and Nigeria in June and July 1959. While it is largely concerned with the public services in Nigeria and the Southern Cameroons, its clear analysis, including a detailed discussion of the movements which took place in Nigeria and Ghana, is designed to ease the transition for territories reaching independence in future, and to suggest what more might be done beforehand to that end. The difficulties and obligations of the Colonial Power are fairly discussed, but to the professional man the great interest of the book lies in its discussion of the future role of the Overseas Service, and the possible forms which such a Service could take if it is to encourage Civil servants, including scientists and other professional men, to remain in the overseas field. Even for professional and technical officers whose services are likely to be needed longer than those of their administrative colleagues, he is doubtful whether such a Service can be provided on a Commonwealth basis. Adequate career prospects, he suggests, can now be found only in an international organization.

While Mr. Younger considers that it would be sound policy for Britain to participate increasingly in the work of the United Nations and other international bodies in this field, this is not the only possibility. The launching of the British Overseas Civil Service has largely been frustrated through the anxiety as to whether the United Kingdom Government now has direct control over a sufficient range of territories to be able to guarantee a life-time of employment abroad. If, however, ways were found of encouraging men, whose careers would basically be pursued at home, to regard periods of overseas service as a normal and advantageous feature of their professional lives, this difficulty would disappear. Furthermore, it is easier for a technical man to keep abreast of modern knowledge if he retains his home base than if he spends his whole career in territories on the periphery of technical advance.

Present arrangements do no more than make it just possible for a keen man in the British public service to serve abroad for a period, albeit at some risk to his career, though a start has been made in the field of education to improve this. If, however, encouragement of overseas service were explicitly adopted as a part of government policy, a big change could probably be effected at very small cost. As Mr. Younger points out, it is primarily a change in attitude that is required, and especially in that of the Civil Service in Britain. Apart from this, he suggests the creation of an agency in Britain outside the framework of Colonial administration, which can give help to dependent and independent areas alike, and by pursuing simultaneously both these methods Britain would be making the best use of her accumulated experience and contributing at the same time to international co-operation and to the stability and development of new States.

Very clearly some fundamental thinking, as well as a change of attitude, is required, if Mr. Younger's suggestions are to be adopted and errors of the past corrected. It is not simply a matter of education policy and development in the Commonwealth, or even of the more effective training of staff proceeding overseas, either in the Oversea Civil Service or in private employment. The contribution and function of the Colonial Development Corporation must obviously be taken into account, as well as that of Barclays Bank D.C.O., Unilever, Ltd., and other firms that take great care in training staff for overseas; but besides the Government responsibility for seeing that the conditions offered for service overseas are reasonable and attract officers of the highest quality, it is also important that the quantitative demand, especially for scientific and technical officers, should receive due attention in assessing the demand for scientific and technical man-power and in determining the provision to be made to meet that demand. This was a notable omission in the last report on scientific and engineering man-power in Britain, and the omission indicates one of the failings of Government policy to which Mr. Younger directs attention. His criticism, however, is on the whole so constructive that it is to be hoped that the Government will respond swiftly to the challenge it offers, and provide alike the increased resources and the measures which the new situation demands, the critical importance of which has been underlined by all the subsequent events in the Congo.

FERRIMAGNETISM IN THEORY AND PRACTICE

Ferrites

Physical Properties of Ferromagnetic Oxides in Relation to Their Technical Applications. By J. Smit and H. P. J. Wijn. Pp. xiv+369. (Eindhoven: Philips' Technical Library, 1959.) 72*s*.

THE history of the growth of our knowledge of ferrites offers an excellent example of the conditions which are becoming increasingly necessary for success in present-day physical research. Following Néel's original theoretical conceptions of ferrimagnetism, the study of these materials was carried on mainly in an industrial organization, furnished not only with the necessary technical prowess to ensure proper sample preparation and purity control, but also endowed with a liberal policy towards basic research. Alongside this work the key to a fuller understanding emerged from government-sponsored laboratories, by means of the technique of neutron-diffraction which had grown up as a by-product of the operation of nuclear reactors. As a result of this combined attack by physical, chemical and crystallographic methods, many of the properties of ferrites are now much better understood than those of the ferromagnetic metals.

Against this background Drs. Smit and Wijn give an account of the basic magnetic properties of ferrites, emphasizing the properties which are of importance for practical applications and with particular reference to the chemical composition and crystal structure of their materials. They emphasize that they are writing at an intermediate level for readers who are actively working with ferrites, and especially in connexion with their technical uses. As a result the opening chapters, which as Part *A*, "Theory", form almost one-third of the book, concentrate on explanations given in terms of simple physical models rather than strict mathematical demonstrations. Many readers will indeed welcome this and will find that these early chapters offer a very readable account of current conceptions in magnetism, viewed in a field much wider than that of ferrites and presented in an original manner.

Succeeding sections of the book are Part *B*, "Methods of Measuring the Ferromagnetic Properties", and *C*, "Intrinsic Properties", which considers in turn the three classes of ferrite with spinel, hexagonal and garnet structures respectively, and describes their chemical composition, crystal structure, saturation magnetization and crystalline anisotropy. One can complain that the garnet class—particularly those containing rare-earth oxides—get rather scant mention compared with the hexagonal group, where the authors do justice to Braun's elegant work which unravelled the structural secrets. In the last third of the book, Part *D*, entitled "Polycrystalline Ferrites", we come to the more purely technical data for the sintered polycrystalline product as normally handled, a macroscopic product the mechanical and electrical properties of which will depend on porosity and any crystallite orientation induced during the manufacturing process. An idea of the very comprehensive discussion in this section is provided by some of the section headings. There are, for example, sections on the frequency-dependence of the conductivity, dielectric constant, permeability and magnetization curve and on the effect of mechanical stress on the magnetic spectrum and the hysteresis loop. The data here, as indeed throughout the book, are presented very clearly in graphical and tabular form.

The book is excellently produced and pleasant to read, though perhaps with more than its fair share of trivial proofing errors which have escaped detection. As a personal feeling I must admit to a dislike of the system of referencing, using forms such as *Ab* 1 and *Ze* 1 which necessitate turning to the back of the book in order to discover the year of any particular publication. Finally—as a suggestion—the less-specialized reader, who may peruse a good deal of this book with profit, might welcome a few notes on the actual employment of ferrites in electronic devices.

G. E. BACON

ENERGY FOR THE ATMOSPHERE

Turbulent Transfer in the Lower Atmosphere

By Dr. C. H. B. Priestley. Pp. vii+130. (Chicago: University of Chicago Press; London: Cambridge University Press, 1959.) 28*s*. net.

THE meteorologist is vitally concerned with the rate at which energy enters or leaves the atmosphere at the surface of the Earth because this flux ultimately provides the major control on the behaviour of the atmosphere up to quite high levels. Momentum is also drained from the atmosphere at the surface; while man, beast and plant lives (or fails to live) in the layer of air immediately affected by these fluxes. They are mainly, for momentum and latent heat wholly, effected by atmospheric turbulence, except at the very boundary, and Dr. Priestley has written a monograph describing the present position of the study of these turbulent transfers. As the leader of a notable group on the subject near Melbourne over most of the post-war period he is admirably fitted to undertake the task.

Priestley begins at the stage reached by the subject in the early post-war years, as expounded by Sutton in his "Micrometeorology". He sets out to provide a coherent body of knowledge on the relation of the vertical fluxes of heat, matter (evaporation) and momentum to the 'external' parameters—the choice of these is quite a part of the problem, particularly as they are affected by the density or thermal gradient, or, from the other end of the telescope, by the heat transfer itself. The simplest condition, that obtaining when the transfer properties of turbulence are not significantly affected by buoyancy forces (non-adiabatic lapse-rate), is now moderately well understood and described, though the flux of heat or water vapour has not yet been adequately related to the actual surface temperature or vapour pressure. For heat, a second special case obtains when the transfer properties of turbulence are dominated by buoyancy forces to the exclusion of shear-engendered forces—the regime of free convection—and here Priestley's dimensional analysis of the problem and the observations of his group provide the required relations. In the general case, however, where both the above forces are effective and all the fluxes are concerned, theory is somewhat halting, but a framework for observation has been provided and the Melbourne observations of fluxes begin to fill the frame. If Priestley is correct, this general case is not of outstanding practical importance for upward heat transfer because he argues for a quite narrow zone of conditions between the regimes on either side.

The evidence on these matters is skilfully assembled and discussed by the author. He also presents a theory of buoyant motion which is cogent and well supported by the experimental record so that mechanism begins to appear. The bridge has yet, however, to be built to the more fundamental approach adopted in recent years by W. V. R. Malkus in which disposable constants do not appear—this work is not referred to by Priestley. Not the least valuable part of the author's work is to relate the surface fluxes to the larger-scale motions of the atmosphere and to the problem of air-mass modification.

This is an excellent monograph for those with some familiarity with the subject of turbulent transfer, not necessarily in the atmosphere. It is thus to be recommended not only to meteorologists but also to practically all fluid dynamicists concerned with boundary layer problems. They will find writing which is primarily physical in approach and only so much mathematics as is needed to make the physics effective. The writer is a notably good apologist for his own cause, and the reader's enjoyment and stimulus should come in part from reacting to the writer's essence. No serious misprints have been noted and the book is nicely produced.

P. A. SHEPPARD

THE WORLD AROUND US

The World around Us

Edited by Sir Graham Sutton. (Six Essays based upon the Christmas Lectures delivered at the Royal Institution, 1958.) Pp. vi+122. (London: The English Universities Press, Ltd., 1960.) 16s. net.

THE 1958–59 Christmas Lectures at the Royal Institution were planned to mark the close of the International Geophysical Year, and this collection of essays based on the Lectures tells of the kind of work that geophysicists do, and describes some of the projects undertaken during the Year. I have never been able to understand the difference between a 'juvenile auditory' and 'teen-agers', or why it is that the former flock eagerly to hear lectures of the highest excellence by outstanding scientists, and the latter are cynically fobbed off with commercialized intellectual fare which could be described as abysmal if it were not certain that there are lower depths yet for future dredging. The answer is, I suppose, that chance is a fine thing. The regular publication of the Lectures brings them annually before a wider and equally eager audience; and as a most attractive book at about half the price of a long-playing record, this present volume should become the best-seller it deserves to be. It gives young people what they really want when they get the chance to choose it.

The first essay, by J. A. Ratcliffe, describes the exploration of the electron density in the ionosphere by radar echo-sounding, satellite transmissions, and observations of whistling atmospherics. J. M. Stagg describes the general features of the Earth's magnetic field, the complex interplay of surges in the Earth's liquid core and effects from outside, particularly the emissions from solar flares. R. L. F. Boyd writes on the information obtained about the upper atmosphere from rocket experiments and instruments carried in rockets and satellites. Sir Graham Sutton, who has edited the book, deals himself with the lower atmosphere and its weather. G. E. R. Deacon's account of oceanography presents a general picture of the scope of a science that ranges from the detailed recording of variations in mean sea-level to harbour design, tidal waves, and the tracking of deep sea currents. G. de Q. Robin describes the problems of establishing and maintaining an antarctic base, and the work done at Scott Base as part of the programme of the International Geophysical Year.

The authors and editor are to be congratulated on transmuting the Lectures into essays that reach the highest level of popular interpretation. They contain so much information that is really new to the ordinary scientist who has not followed the march of events closely, and should be widely appreciated on this account as well. The publishers also must be congratulated on the production.

G. R. NOAKES

EXPLORING VECTOR SPACE

Vector Space and Its Application in Crystal-Structure Investigation

By Prof. Martin J. Buerger. Pp. xiv+347. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1959.) 96s. net.

PROF. D. KOSAMBI, the Bernal of India, has written a collection of articles entitled "Exasperating Essays". It would make a very suitable second title for Prof. Buerger's "Vector Space and Its Application in Crystal-Structure Investigation". The book is exasperating because the subject is of vital concern to X-ray crystallographers, endeavouring to piece together the jig-saw puzzle of their experimental data, and yet one cannot help feeling that the really significant aspects could be presented in a smaller compass and made easier to assimilate.

The crystallographers' jig-saw puzzle, when the pieces are finally fitted together correctly, gives a picture of the electron-density distribution in the crystal, the peaks corresponding to atomic positions. Unfortunately the pieces will fit together in many different ways, and the key, the phase angle of the diffracted X-ray beam or the number on the back of the piece, which would enable the picture to be built up directly and systematically, has been obliterated. There is no means yet known by which the relative phases of diffracted X-ray beams can be determined directly, and it is this 'phase problem' of the structural crystallographer which is responsible for the study of 'vector space'. The concept originated in 1934 when Patterson showed that a modified jig-saw puzzle could be constructed directly from the experimental data, but that the picture so constructed was the 'vector set' derived from the actual atomic arrangement. That is, all the possible vectors between atoms are constructed and one end of each is then transferred to the origin. In general, there are n^2 peaks in the vector diagram derived from n atomic positions, and the problem resolves itself into the 'unsquaring' of this distribution of vector peaks.

Prof. Buerger has played a prominent part in the gradual development of systematic methods of tackling this problem, and the present book presents a survey of these methods, many of which the author has himself originated. It may be said that the book is too complete and insufficiently critical, but another of its exasperating aspects is that one cannot really apportion any blame for this. It is by no means yet clear which methods are going to be most fruitful in exploring vector space, and very little beyond an intuitive idea that the two methods are more or less equivalent has yet been said on the relation of vector methods to the alternative determination of phases by the statistical analysis of the raw data. In these circumstances, to have all the fundamental ideas on vector space and the various analytical methods brought together (and developed) in one book is really as much as one has a right to expect, and something for which all X-ray crystallographers owe Prof. Buerger a debt of gratitude. The criticisms that one has are largely silenced and, exasperating or not, this book will be required reading for all those concerned with Patterson analysis for a long time to come. J. W. JEFFERY

POTASH IN WET AND DRY SOILS

Japanese Potassium Symposium

Nine papers read at the First Japanese Congress, Tokyo, 1957. Pp. 137. (Berne: International Potash Institute, 1959.) n.p.

Potassium Symposium, 1958

Twelve papers read at the Fifth Congress of the International Potash Institute (4 Sessions), Madrid, 1958. Pp. 426. (Berne: International Potash Institute, 1959.) n.p.

SINCE its inception in 1952, the International Potash Institute (Berne) has rendered a valuable service to agriculture and agricultural research. As well as issuing the monthly *Potash Review* leaflets in four languages, the Institute has organized five potassium congresses in different European capitals over the years 1954–58. The Institute also instigated a Japanese potassium symposium, held in 1957; the nine papers presented in Tokyo are now reprinted in English. Four of the papers deal, not surprisingly, with potash and the rice crop. Students of rice culture will find factual articles which range from fertilizer usage to the relationships between potassium nutrition and the disorders caused by fungus and bacterium attacks on the crop. A paper on fruit trees deals specifically with the effects of fruiting on the composition of young orange tree leaves. The nutrition of tobacco is discussed in terms of deficiencies and excesses of potassium on the intake of other nutrients. Recent work on the distribution and lability of potassium in cells and the effect of different potassium-levels on respiration is also described. The reasons for the variations in the potassium-supplying power of volcanic ash soils are examined; usually the parent volcanic ash contains rather little total potassium, which is lost rapidly on weathering. The main products of weathering, allophane, halloysite and gibbsite, do little or nothing to help the potassium economy of such soils. All the papers seem to be well documented.

The volume entitled "Potassium Symposium, 1958", contains the proceedings of the fifth congress of the International Potash Institute, held in Madrid. Following an introductory paper on Spanish agriculture and the use of fertilizers, most of the contributions impinge on the general theme of "Potash and Water". Special attention is given to the potash manuring of Spanish irrigated areas and potassium problems related to the mineralogy of Spanish soils. Three articles deal with potassium, the plant and the water regime; these include treatments of the morphological and physiological conditions associated with drought resistance, the influence of potash on the water economy of plants and the effects of extracts of rotted straw on the potassium uptake and physiology of plants. Other articles deal with potassium uptake and the moisture status of soils (England), potassium in saline soils (Spain) and the importance of potassium in saline irrigation water (Israel). The papers presented towards the end of the Congress allow comparisons of the problems of potash fertilization in temperate, arid and wet-tropical climates. The development of fertilizer usage in the Hawaiian sugar industry is also described; here potash-urea pellets are now hailed on the cane from the air. Readers will find short articles on the use of potash in Portugal, chlorosis and calcium/potassium ratios and the use of potash on rubber trees.

The main articles, which are well documented, are all summarized in four languages.

Having circumscribed the globe, one's thoughts gravitate towards the numerically enormous number of the world's farmers who have yet to open their first bag of potash. The International Potash Institute will, year by year, make these fewer and so help mankind towards a happier existence by encouraging the proverbial two blades to grow where one grew before. P. W. ARNOLD

PLANT TISSUE CULTURES

La Culture des Tissus Végétaux

Techniques et Réalisations. Par Prof. R. J. Gautheret. (Ouvrage publié avec le Concours du Centre National de la Recherche Scientifique.) Pp. iv+884. (Paris: Masson et Cie., 1959.) Cartonné toile, 10,500 francs.

FOR a considerable time following the first successful culture of plant tissues in 1934, further studies of such materials were carried out mainly by a few pioneer workers. During recent years, however, there has been a great widening of interest in plant tissue cultures, which are now no longer treated merely as curiosities but are utilized in the investigation of a wide range of botanical and related problems. The scattered information obtained from these recent and earlier studies has now been collected in one comprehensive volume, and it is fitting that this task should have been carried out by Prof. Gautheret, who was not only the first worker to achieve the culture of plant tissues but by his own work and that of his pupils has also continued to make notable contributions in this field.

As the title indicates, the book deals only with tissue cultures, and the allied subject of organ culture is mentioned only incidentally. The first section, of more than 200 pages, covers the important topic of technique. The media and methods employed by various workers are described in full detail, perhaps even unnecessarily so; the reader is given several plans of the arrangement of instruments on the work table. However, such detailed instructions have the advantage of giving even the beginner in this line of work a good chance of success.

The second and largest part of the book is concerned with morphogenesis in plant tissue cultures. A detailed description is given of the behaviour of tissues when first placed in culture, and of the morphology and development of established strains. There is also an excellent treatment of the differentiation of tissues and organs in various cultures, an aspect of plant tissue culture which has probably yielded the most interesting results to date.

Other sections deal with the utilization of tissue cultures in various special studies. Thus, the use made of tissue cultures in the study of polarity and induction is described. This is followed by an extensive consideration of the nutrient requirements of plant tissues. It is pointed out that although the tissues of many plants can be grown on purely synthetic media, other tissues can only grow, or grow better, following the supply of various plant extracts such as coconut milk. This section includes a full account of the attempts at isolation of the active factor or factors, accompanied by a careful analysis of the difficulties encountered in such work. In this connexion, Prof. Gautheret emphasizes the necessity of working with a suitable tissue strain, of known behaviour, as assay material. In this type of work, as in various metabolic studies of tissue cultures, it is important to note that freshly excised tissues show marked metabolic disturbances and may differ considerably in behaviour from established stocks.

Other topics dealt with are the culture of isolated cells, which is a very recent development, and the role of tissue cultures in plant pathology. With reference to the latter section, mention may be made of the use of tissue cultures in the culture of obligate parasites, and of a particularly interesting account of plant tumours.

In sum, this book is a fine comprehensive account of all aspects of plant tissue cultures. For a work of its size it is remarkably up to date, a supplementary bibliography including most of the important literature issued during 1958. It is well illustrated, the 438 figures including photographs, diagrams and line drawings. Although bulky, the book is easy to use, a clear subdivision of the contents facilitating the location of any particular topic. There is also a useful table of the principal established strains of plant-tissue cultures, which includes a summary of any special nutrient requirements of the various tissues.

A. Allsopp

COMBATING THE DECAY OF TIMBER

Decay of Timber and its Prevention

By K. St. G. Cartwright and W. P. K. Findlay. Second edition. Pp. xv+332+57 plates. (London: H.M. Stationery Office, 1958. Published for D.S.I.R.) 27*s*. 6*d*. net.

Decay of timber must have been a perpetual problem since man first began to use wood, and a serious one as soon as wooden structures became elaborate. We know of the trouble and expense which faced the Navy as a result of the ravages of dry rot in the days of wooden ships, while in buildings decay of timber began to receive serious attention at the beginning of the nineteenth century, coincidently, no doubt, with the decline in the use of the traditional oak in favour of less-durable coniferous woods.

Nevertheless, with the exception of Marshall Ward's "Timber and some of its Diseases", which was based largely on German work, "Decay of Timber and its Prevention", by K. St. G. Cartwright and W. P. K. Findlay, of which the first edition appeared in 1946, seems to be the first comprehensive account of the subject to be published in Britain. It embodies much material based on the authors' investigations at the Forest Products Laboratory at Princes Risborough.

Following introductory chapters on decay in wood, and on the causal organisms, there are detailed accounts of the principal rots of standing trees, accompanied by useful tables concerned with macroscopic and microscopic features of the rots and the characteristic features, in culture, of the causal fungi. Felled timber and wood in outdoor use receive similar treatment, as does constructional timber in buildings and elsewhere. Preventive measures are described, particularly in reference to felled and converted timber and to timber in use. Decay in plywood, wood pulp and building boards receives consideration, and there is a valuable summary of present knowledge of stains and discoloration of timber. There are numerous illustrations, and those of the characteristic appearance of certain rots make a specially valuable supplement to the text and should greatly facilitate identification.

Although a comprehensive treatise, there are times when the information sought is scant and vague. This is no reflexion on the diligence and care of the authors, but rather on the large gaps in knowledge of these interesting and troublesome organisms and their activities. It is indicative of the enormous field of research which awaits the investigator, more particularly with reference to the rots and staining fungi of tropical areas. For any such research the book in question is certain to be a standard work of reference.

F. W. Jane

ANIMAL EXPERIMENTS IN RESEARCH

Achievement

Some Contributions of Animal Experiment to the Conquest of Disease. By Dr. Geoffrey Lapage. Pp. viii+255. (Cambridge: W. Heffer and Sons, Ltd., 1960.) 18*s*. net.

This is an unexpected, original and wholly admirable book. It could have been attempted by a journalist with a smattering of science, but it was, in fact, written by a scientist who has a considerable ability for writing. In view of the seriousness of the subject this is a piece of good fortune for the reader, while implying no derogation of the art of journalism.

Animal experimentation is not often discussed in respectable company; not often enough, and still less often without generating emotion. Dr. Lapage's book is in the direct line of descent from earlier books on the same subject by Stephen Paget and Leonard Rogers; but the treatment is entirely different. Nowhere is the word 'vivisection' mentioned, and nowhere does the author indulge in polemics or argue the moral case. He is content, and so may the reader be, to tell how animal experimentation has led, as no other method had previously led or could have led, directly to advances in human and animal medicine and their related fields of research. Among the animals used, man himself, meaning nearly always the investigator, has a prominent place in this book, which is as worthy a way of paying tribute to our great men as we could wish for. The author has drawn freely on articles appearing in *Conquest*, the journal of the Research Defence Society, over the past ten years.

A former university lecturer who has written a standard work on parasitology might be expected to have written in the style of a text-book; but Dr. Lapage has avoided this pitfall, without sacrificing accuracy and extensive documentation. The book is outstandingly readable; yet it includes nine pages of bibliography and a further nine of index.

There is so much to applaud in this dispassionate treatment of an emotive subject that even to suggest imperfections might be thought ungracious. The emphasis on infectious diseases—three chapters out of ten—is easily defended, for they represent medicine's greatest achievements to-day. Chemotherapy, hormones, nutrition and deficiency diseases are, *inter alia*, also well treated. The absence of a foreword is regretted, all the more because the preface is so short. I discovered only two misprints.

The wise refusal of the author to discuss the moral question is the best reason of all why this book should be compulsory reading for all who recognize that, in animal experimentation, a moral question exists.

The presentation conforms to the high standard one has come to expect from the publishers.

W. LANE-PETTER

SCIENCE FOR THE FAMILY

Science

Chemistry, Physics, Astronomy. Editorial Board: Dr. J. Bronowski, with Sir Gerald Barry, James Fisher, and Sir Julian Huxley. (The Macdonald Illustrated Library.) Pp. 367. (London: Macdonald and Co. (Publishers), Ltd., 1960.) 45*s*. net.

THIS is the first volume of a library of knowledge written for young readers and their parents. The book is so arranged that each double page forms a separate article. This arrangement has distinct advantages over an alphabetical one, and considerable care and thought have been taken in planning the order of the articles so that the book presents a coherent whole. There are a comprehensive glossary as well as an index. In addition, several useful references occur incidentally in the list of illustration credits; but, in a book where much of the information is of necessity superficial, a more systematic bibliography would surely have been welcomed by many readers.

The text is copiously illustrated with excellent diagrams, prints and photographs, containing information complementary to that of the text. There are also several full-page illustrations in colour by Hans Erni which, while being delightful and of high artistic merit, seem unlikely to aid the young reader in his understanding of the subject-matter.

The book unfolds the story of the advancement of the physical sciences from very early times up to the present day, including topics such as polymers, atomic power, television and satellites. A judicious and comprehensive selection has been made, and wisely no attempt has been made to introduce subjects which could not be explained adequately in elementary terms. There is a commendable lightness of touch (not always to be found in works of an encyclopædic nature) in the text, though occasional lapses do occur. For example, we are told on p. 126 that "work is done only when the force acting on a body moves that body in the direction of the force". On p. 128 the reader is apparently encouraged to use "weight" as synonymous with "mass". It is stated on p. 232 that, for a convex lens, "nearer the center . . . the rays are bent less sharply" and on p. 233, for the same lens, that "the lens bends rays that pass near its center more than rays that pass near its edge". The machine shown on p. 121 has mechanical advantage 3, and not 4 as stated. Very few misprints were detected, but the young British reader needs warning that, the book being "international in scope", an American system of spelling has, perhaps unfortunately, been adopted.

These are only minor criticisms. The distinguished editorial board, and all others concerned in its production, are to be complimented on a volume of high quality which will undoubtedly give hours of enjoyment to many readers both young and old. It would surely prove a popular addition to any school library.

D. R. DICKINSON

THE HIDDEN MIND

The Wish to Fall Ill

A Study of Psychoanalysis and Medicine. By Karin Stephen. Pp. vi+238. (Cambridge: At the University Press, 1960.) 10*s*. 6*d*. net; 1.45 dollars, paper bound.

THIS book is an excellent introduction to psychoanalytical theory. It has been based on lectures given to medical students at the University of Cambridge and so is comprehensible to those who have little or no psychiatric knowledge. The author draws on her clinical experience and the cases she quotes add interest to the theoretical descriptions.

Dr. Stephen commences with a discussion of the origin of the unconscious in disappointment, conflict and repression, and describes how this is solved by illness. She shows the obstacles in the way of investigating the unconscious and how psychoanalytical technique uses free association to penetrate this barrier.

Having shown the difficulties to investigation she passes on to describe what is found once we are able to lift the lid of the mind, as it were, and see what is underneath: the primitive sexual nature of the unconscious, infantile pleasure-seeking by mouth, excretory pleasure-seeking and phallic-pleasure seeking.

This naturally leads on to the fears of being deprived of such enjoyment—to the Oedipus complex and castration fears; the arousal of anxiety and guilt, and defence mechanisms; finally, the use of transference in treatment.

Many people, even now, have little or no idea what the analyst is trying to do or how he produces cures. Properly conducted analysis is much more scientific than is often appreciated and the process is more related to observing any other natural phenomena than to patting someone's hand and telling him all is well—which is the popular idea of the process.

CLIFFORD ALLEN

Nature and Man

By John Hillaby. (Progress of Science Series, No. 9.) Pp. 64+28 plates. (London: Phoenix House, Ltd.; New York: Roy Publishers, 1960.) 9*s.* 6*d.* net.

ANY series of books designed to help young people to keep up with the progress of science deserves encouragement. In one of this new series, John Hillaby, European science correspondent of *The New York Times* and zoological correspondent of *The Guardian*, has attempted to show the perpetual struggle between man, animals and plants and how the balance of Nature often becomes greatly disturbed from what seem trivial beginnings. From his travels in many parts of the world Hillaby has seen the awful results which sometimes follow the upsets to natural life and records these in tense and dramatic style.

Among the topics described are the blocking of the Congo River by the devil's lilac and the expenditure of £3 million on chemicals to clear it for traffic; the fearsome effect of too many lemmings, musk-rats and rabbits and other animals; soil-erosion (unfortunate, perhaps, that Hillaby had to go to Athens to witness a soil-storm when his own native Pennines are being deposited in Sheffield and other cities); and the consequences of over-shooting big game.

There is also a chapter on the ways in which young people can train for careers in the conservation of Nature. Whether the author is right to pitch a book with this approach to young people of "12 and upwards" is very questionable. In many secondary modern schools the suggestion that Elton's "Animal Ecology" could form useful further reading for children of this age would receive a not unjustified rejection.

T. H. HAWKINS

Principles of Sugar Technology

Edited by Pieter Honig. Vol. 2: Crystallization. Pp. xviii+567. (Amsterdam: Elsevier Publishing Company; London: D. Van Nostrand Company, Ltd., 1959.) 95*s.*

THIS volume was produced by a selected group of experts as with the first volume. There is a vast mass of useful material to be found in these pages and there is little to be criticized. The crystallography of sucrose might have been improved by the incorporation of some of the useful work done in the University of Bristol, namely, by N. Albon and W. J. Dunning (see *Nature*, 180, 1348; 1957). This was on growth steps of sucrose crystals. Further work was not then published, but is to be found in the thesis of N. Albon at Bristol. Also in Doremus, Roberts and Turnbull (Wiley, 1958) and in *Acta Crystallographica*, Honig directs attention to the loss by inversion on solutions above 65° Brix, as being greater than given by the Stadler tables. He also mentions that pan work actually gives an increased amount of loss of sucrose progressively from affination syrup, first crop, and second crop. The invert produced was lower progressively, showing that combination had taken place. The use of symbols is misleading; C.V. is used for crystallization velocity without explanation, whereas C.V. is already used for the coefficient of variation. A few spelling mistakes occur, including, p. 193, "fosfation". These are poor examples of an otherwise very good book. It is one that should be on the shelves in all sugar factories, refineries and head offices, and should be utilized for new work as well as for judging everyday work.

H. C. S. DE WHALLEY

Les Modèles du Noyau

Par Michel Trocheris. (Bibliothèque des Sciences et Techniques Nucléaires.) Pp. 152. (Saclay: Institut National des Sciences et Techniques Nucléaires; Paris: Presses Universitaires de France, 1959.) 26 N.F.

THE nineteen-fifties have been marked by a vigorous growth in the theory of nuclear structure and the models used to represent it. This book originated in a series of lectures delivered at Saclay in 1955, and the value of its publication nearly five years later might seem questionable. The subject-matter of this book, however, is by no means as general as its title might suggest; it is concerned with an elementary introduction to some of the techniques used in calculations based on the models considered (the Fermi gas, the shell model and the Bohr–Mottelson collective model), rather than the physics of the models themselves or their detailed application to experimental data. Such techniques are often less time-dependent than the models which suggest them, but the meagreness of physical discussion must inevitably limit the usefulness of the book. A second limitation is the almost complete omission of nuclear reaction and decay properties from the discussion. Such properties are as important to present-day nuclear models as the spectra and static moments.

Within these limits the author has written a clear, elementary account of the subject, and this book may form a useful bridge between an undergraduate course of quantum mechanics and the specialized monographs on the various nuclear models.

J. M. SOPER

Nutzenergie aus Atomkernen

Von Dr. Karl Rudolf Schmidt. (Einfuhrung in Physik und Technik von Kernreaktor und Atomkraftwerk, Band 1.) Mit Beiträgen von Hans Günter Heitmann, B. Logermann und Wolfgang Mayer. Pp. xvi+594. (Berlin: Walter de Gruyter und Co., 1959.) 106 D.M.

OF the many books currently available on reactor science and engineering, this must surely be the most ambitious in scope, dealing as it does with almost all aspects of the subject. Starting with elementary atomic and nuclear physics, it leads on to radiation and radioactivity, particle accelerators, nuclear stability and the chain reaction. This in turn leads to elementary neutron physics, reactor theory and lattice calculations.

To note that the subject of nuclear forces, for example, is dealt with in about half a page is not to criticize the book, since its aim is clearly to serve largely as an introduction to the physics side of the title, while providing a more complete analysis of the engineering and technological side. This latter, which takes up more than half the book, deals very thoroughly with such diverse aspects as chemical separation, ion exchange methods, trans-plutonium elements, thermodynamics (including turbine theory, heat transfer, heat exchangers, etc.) and a long section on the properties of materials of interest to reactor designers.

The text is very well supplemented by tables, graphs, references and even nomograms, but, surprisingly, has no index, while topics like reactor kinetics, fission-product poisoning, and shielding are apparently examined in Volume 2, rather than in the physics part of Volume 1, and reactor stability is ignored entirely.

K. R. E. SMITH

THE IAN CLUNIES ROSS ANIMAL RESEARCH LABORATORY, PROSPECT, NEW SOUTH WALES

By DR. IAN W. McDONALD
Chief, Division of Animal Physiology, Commonwealth Scientific and Industrial Research Organization, Australia

THE dominant role of the sheep industry in Australia's economy has naturally influenced the trends of agricultural research. During the early phase of research sponsored by the State and Commonwealth Governments, attention was focused primarily on the control, treatment or prevention of the numerous diseases which impaired the productivity of flocks. As effective procedures were steadily acquired, it became clear that there was scope for equally useful research on the productivity of sheep. Plans for such a development had gradually been matured by the late Sir Ian Clunies Ross (chairman of the Commonwealth Scientific and Industrial Research Organization), Dr. L. B. Bull (then chief of the Organization's Division of Animal Health and Production) and Mr. H. B. Carter (now with the Animal Breeding Research Organization of the Agricultural Research Council in Britain). The funds to initiate the project were made available by the Australian Commonwealth Government through the Wool Use Promotion Act of 1945 and the Wool Industry Fund Act of 1946. More recently, additional financial aid has been provided directly from the sheep industry by a levy on wool.

A site of 116 acres was acquired at Prospect, a village twenty miles from Sydney, where some of the earliest farms in the first Australian colony were established. The Laboratory, originally called the Sheep Biology Laboratory[1], was gradually developed over the years 1953–59, and was staffed by research groups which had been temporarily accommodated in sister laboratories. The main laboratory block, shown in Fig. 1, was completed in 1959 and officially opened on March 9 by Lord Casey, who until his recent elevation to the peerage had been the Minister-in-Charge of the Commonwealth Scientific and Industrial Research Organization.

As a tribute and a memorial to Sir Ian Clunies Ross, who had contributed so much to the sheep and wool industry through his own research as well as his official direction of the research organization, the Laboratory was renamed the "Ian Clunies Ross Animal Research Laboratory".

The Laboratory was initially directed, on a part-time basis, by Dr. C. W. Emmens, professor of veterinary physiology in the University of Sydney. In 1955, I was appointed officer-in-charge, and an assistant to the chief of the Division of Animal Health and Production, Mr. D. A. Gill. On the retirement of Mr. Gill in 1959 this Division was reorganized and I was appointed chief of the new Division of Animal Physiology, of which the Clunies Ross Laboratory plays the major part.

The present staff includes 42 graduates and 56 technical assistants. The main building contains 24 laboratories of modern design with full service facilities and air conditioning, a comprehensive library, conference room and administrative offices; the floor area is about 25,000 sq. ft., and the cost of construction was £A.240,000. Two large animal houses accommodate 300 sheep in single pens, while another 700 sheep are run out-of-doors. The usual small laboratory animals, used primarily for bio-assays, are housed in fully air-conditioned rooms. A

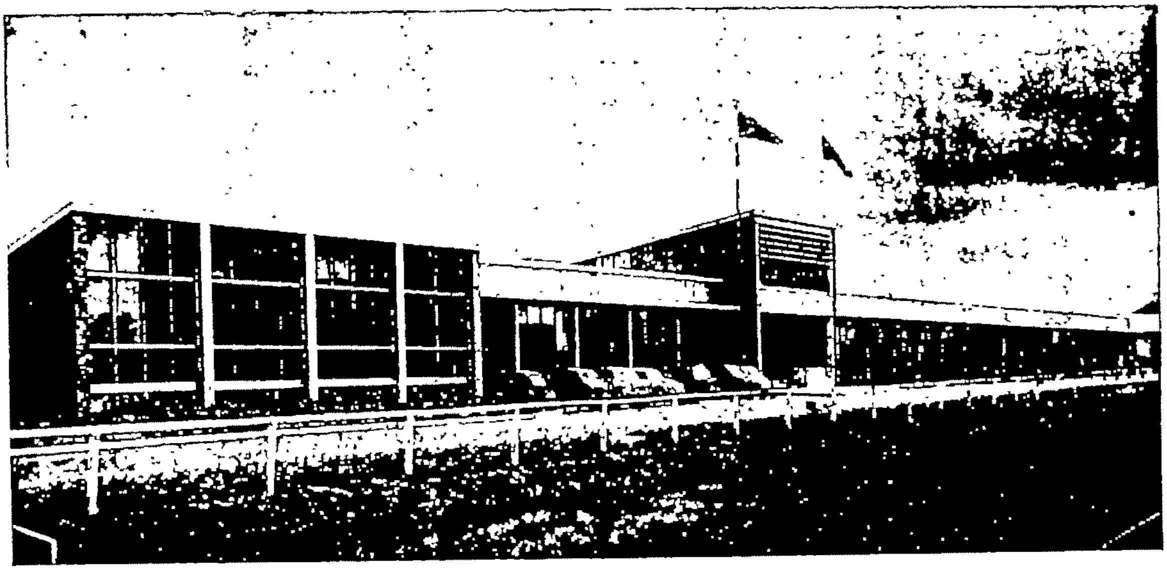

Fig. 1. The Ian Clunies Ross Animal Research Laboratory

modern operating theatre caters for experimental surgery. A number of small fields with sown pasture provide for 'pilot scale' studies on the grazing animal. A well-equipped workshop constructs and maintains much of the special equipment required.

The use of radioactive isotopes in animals as large as the sheep poses some special problems in protection of personnel and disposal of wastes. To meet these problems, an isolated block is being built with accommodation for experimental animals and specially fitted laboratories for handling highly radioactive preparations and for initial processing of biological samples. Laboratory equipment has been provided for preparative and analytical work. Amino-acids labelled with sulphur-35 have proved especially valuable in work on wool growth, and chromium-51 has found application as a marker in studies on digestion. Tritium, carbon-14, iodine-131 and phosphorus-32 have also been used in familiar biological techniques.

The work of the Laboratory falls into seven main categories: reproduction, endocrinology, intermediary metabolism, dermology (morphogenesis, structure and function of the skin), bioclimatology, nutrition, and ecology. The objective has been to expand knowledge of the special physiology of the sheep, with emphasis on those aspects which are likely to lead to more efficient productivity of healthy animals. Sheep are reared under the most diverse conditions in Australia—from the semi-arid, tropical regions of central Queensland, through the temperate grasslands of New South Wales, the tablelands of the Great Dividing Range, to the cool temperate, high-rainfall zones in Tasmania; from pastures so sparse that 10 acres may be allotted to each sheep, to rich highly developed pastures carrying several sheep per acre. With such diversity, it is difficult to generalize on the topic of animal husbandry. As a consequence, the research programme has been designed to provide a sound physiological basis on which husbandry procedures, appropriate to each of the many special regions, can gradually be developed. Some illustrations from recent work are given in the following paragraphs.

It has been known for some time that exposure of rams to high ambient temperatures may lead to seminal degeneration. The mechanisms regulating testicular temperature show very interesting features. The long, coiled, spermatic artery is in intimate contact with a venous plexus, forming a complex which greatly reduces pulse pressure in the artery, and which acts as a highly efficient heat-exchanger. The large temperature gradient between aortic blood and testicular tissue (some 5–6° C.) appears to be derived from scrotal heat loss, and the arterio–venous relations permit the afferent arterial blood to respond quickly to changes in scrotal temperature. It is probable that the efficiency of the scrotum as a heat-dissipating structure is a major factor determining the fertility of the ram in periods of high environmental temperature.

Fertility of ewes has been examined from several angles. The well-defined sexual season of breeds developed in high latitudes is not found in Merino and cross-bred sheep, many of which do not show a definite anoestrus period. The British breeds enter their breeding season in response to declining hours of daylight; but this cannot explain the activity of Merino ewes which may enter their breeding season in the spring with increasing hours of daylight. Clearly other factors, including ambient temperature, must be involved. Climate also influences the frequency of twin ovulations in the ewe. Experiments are being conducted under controlled conditions of light and temperature in the Laboratory to unravel these environmental factors and to determine the physiological pathways by which ovarian function and sexual activity are influenced.

The occurrence of oestrogens in pasture plants was first observed some years ago in Western Australia and has recently been observed in eastern States. This can lead to infertility, dystokia or neonatal deaths to a serious degree, and attempts are therefore being made to develop bioassay techniques as a preliminary to further investigation of the problem. Ovariectomized ewes and wethers appear to be promising material for this study.

Artificial insemination in bovines has been developed, in many countries, to a highly successful, routine procedure; in the sheep, however, the technique has proved less satisfactory. One achievement required for successful application is the induction of oestrus and ovulation at a pre-determined time; procedures for this are being developed; but for reasons not yet clear, fertility has remained rather low. The processes of sperm transport, fertilization and implantation are being examined to throw light on possible interference with fertility.

The metabolism of the pregnant ewe has been the subject of extended study. It has been shown that a number of factors contribute to make the ewe highly subject to nutritional and environmental stresses in late pregnancy, terminating in death of the ewe with pregnancy toxaemia or the birth of weak lambs with high neonatal mortality. The limited supplies of glucose available for absorption from the gut, the preponderance of volatile fatty acids as sources of energy, and the efficiency of the foetal lamb in withdrawing maternal blood glucose, all predispose to a physiological hypoglycaemia; this, in turn, leads to hepatic inadequacy and adrenal hypertrophy, which permits, under appropriate stress, great increases in circulating corticosteroids, the development of a diabetic state, and profound interference with the central nervous system. Only the outlines of these metabolic inter-relationships have yet been established—much remains to be learnt of the factors governing appetite, digestion in the pregnant ewe, gross energy transactions, the major metabolic pathways, the demands of the foetus for glucose and amino-acids, the capacity of sheep tissues for gluconeogenesis, the endocrine control of metabolism and the sequence of events leading to metabolic failure.

The new-born lamb arrives into an environment that is all too frequently hostile; it is perhaps scarcely credible that, even in the tropics, lambs may die from cold stress. There is a formidable list of infective diseases which account for much lamb mortality, but many controlled observations have shown unequivocally that, in Australia, most deaths in new-born lambs can be attributed to exposure and/or inadequate nutrition. This has stimulated interest in the physiological mechanisms that enable the foetal lamb to cope with its sudden change in environment, the influence of maternal nutrition on foetal development, and the initiation of lactation in the ewe.

The physiological mechanisms governing wool growth have proved to be highly complex. The wool follicles are all formed in the foetal lamb, though not all are producing fibres at the time of birth. Even during fœtal life, the development of follicles can be influenced by maternal malnutrition, with permanent detrimental effects. Maturation of follicles occurs rapidly in the lamb, and with increasing age, the follicles become progressively less susceptible to irreversible damage. The three major fields of interest regarding wool growth are endocrine control, effects of nutritional status and climatic influence. The anterior pituitary gland has the major controlling influence, but the individual hormones responsible have not yet been determined; this work has led to an intensive study of the fractionation of pituitary proteins, which has shown the multiplicity of proteins present in the most highly purified preparations at present available. The adrenal corticosteroids have a strong inhibitory effect on wool growth, while administration of thyroxine leads to enhancement of wool growth. There appears to be no specific effect of the sex hormones on wool growth.

Climatic influence on wool growth is definite, with increase during the summer months and decrease during winter. The relative contributions of day-length, ambient temperature or other environmental factors are being studied experimentally with animals maintained in artificially controlled climates. Concurrently, the seasonal variation in reproductive performance can be studied with the same experimental animals.

Wool growth-rate is very sensitive to the nutritional status of the animal. The fact that wool is essentially a protein 'secretion' led to the justified interpretation of earlier work that wool growth was a function of protein intake. More recent work has shown the curious fact that, provided the protein content of the ration is above a certain minimum level, energy intake dominates the growth-rate. The physiological mechanisms involved here remain to be elucidated. Under natural grazing conditions, the influences of nutrition and climate on wool growth are confounded, and much ecological study is needed to clarify the situation.

Biochemical work on wool growth has been greatly assisted by the use of amino-acids labelled with sulphur-35 or carbon-14. The extremely rapid incorporation of labelled cystine into the growing wool fibre (within 1 mm. after an intravenous injection) has also provided a tool for the precise measurement of rate of growth in length of fibres during short time intervals, and for critical examinations of differential changes in length and diameter within individual fibres.

Nutritional research has been aided by the construction of two respiration chambers. The closed-circuit design has been selected, with automatically controlled conditioning equipment for varying the chamber environment over a wide range and in constant or cyclic conditions. Experimental sheep are housed and trained in an air-conditioned room so that seasonal influences are reduced to a minimum.

For research in bioclimatology, two climate rooms have been constructed, each capable of accommodating fourteen sheep. In one room a wind tunnel has been built, to enable experimental animals or mechanical models to be exposed to controlled conditions of temperature, humidity, wind and simulated rainfall. Apart from studies mentioned above on wool growth and reproduction, the major projects concern the physiological mechanisms involved in cold stress and heat stress.

The Clunies Ross Laboratory is still in a formative stage; but already it is clear that the application of the biological sciences (physiology, biochemistry, histology, ecology) can throw new light on one of the most ancient of man's vocations—the husbandry of sheep.

RECENT SCIENTIFIC ACTIVITIES AT HALLEY BAY: INTERNATIONAL GEOPHYSICAL CO-OPERATION, 1959

By M. J. BLACKWELL*

Introduction

ON January 10, 1959, a twelve-man party of the Falkland Islands Dependencies Survey arrived at Halley Bay to take over the station from the Royal Society's International Geophysical Year expedition[1]. Following the last-minute decision to continue the scientific programme during the International Geophysical Co-operation, a relief team had been hurriedly organized of personnel seconded from outside bodies, including five scientists from the British and South African meteorological services and five technicians from the Services.

The Falkland Islands party had three links with earlier teams: Lieut. G. R. Lush, R.N. (leader) and D. W. S. Limbert had been members of the 1956 advance party, while J. A. Smith remained from the 1958 party. None of the team, however, was able to spend more than a week or two in preparation for polar work; each was entirely dependent on experience gained in his normal professional occupation. An outline of the main activities of the team and a few of the significant results are described below.

Surface Meteorology

Full synoptic observations were made every three hours, and instrumental readings were taken every hour. Because of the accumulation of snow, the anemometer tower needed an extension of 15 ft. A ventilated thermocouple psychrometer, developed by D. Tribble of the International Geophysical Year party, was used throughout the period to give the first complete year of accurate humidity data at very low temperatures. It has a potential accuracy of a few hundredths of a degree in ice-bulb depression and this was more closely realized by adding extra radiation shields. Trials were carried out by D. W. S. Limbert of a phosphorus pentoxide electrolytic hygrometer[5] which is capable of giving a continuous record of absolute humidity below − 20° C. This is the limit below which the conventional hair hygrograph becomes useless[3].

---

* Seconded from the Meteorological Office, Air Ministry, as Chief Scientist, Halley Bay, during the International Geophysical Co-operation.

Upper Air Meteorology

The International Geophysical Co-operation programme provided for one ascent daily. One of the immediate problems facing the team was the maintenance of access to the balloon shed, which was already two-thirds buried by drift snow. An annexe, 16 ft. square, was built in front of the main door and covered with hinged flaps, just above the snow-level. The floor of the cavity thus created led down in easy steps to the old entrance. This arrangement, devised by G. R. Lush, made it necessary to launch the 1,250-gm. balloons out in the open. The radio-sondes and wind-finding radar targets had to be attached, on the run, before the balloons were torn to pieces in the frequent blizzards. By using unwinders with trailing aerials, quick-action clips for attaching the rigs and by dogged teamwork, ascents were achieved on all but 50 days; of these, 46 were gale days. It was surprising that balloons which had been twisted into fantastic shapes during the launches would reach heights of well over 20 km. During the winter months the balloons were dipped in a mixture of lubricating oil and kerosene to prevent premature bursts at relatively low heights. Without this treatment, heights of 10 km. would be typical, whereas 20 km. was consistently reached throughout the winter. Preheating of the balloons also contributed to the excellent performances, which are summarized in Table 1.

Table 1. Mean Heights reached in Upper Air Soundings

Month	Jan.	Feb.	Mar.	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.	Year
Mean ht. (km.)	22·7	23·3	22·5	22·3	19·4	21·3	20·3	21·3	22·4	22·4	22·8	21·9	21·9

In addition to the work of J. A. Smith, who organized the upper air programme, it is a pleasure to record the contributions of our two South African colleagues, G. M. Artz and J. Bothma, who had not previously encountered the British radiosonde or the Decca wind-finding radar equipment.

Other Meteorological Activities

Continuous records were maintained of total and diffuse solar radiation and of total net flux. Additional measurements were made of the short-wave albedo of the ice shelf. A new hut was built for the ozone spectrophotometer. This was mounted on sledge runners to facilitate regular recovery from snow drifts. By sighting the instrument through a small hatch in the roof, observations could be made in all weathers. On one occasion, zenith sky measurements were made successfully in a wind of 55 knots with gusts to more than 70 knots. The development of sledge-based huts for similar scientific activities is one which shows considerable promise for the future. The normal summer observations were linked by Moon observations during the polar night. Six series of *umkehr* measurements were made to investigate variations in the vertical distribution of ozone. It had been observed in previous years[4] that the spring increase in total ozone content was quite sharp at Halley Bay. It is interesting to note that this increase was only gradual in 1959. The discovery of new modes of atmospheric behaviour gives some measure of reward to those responsible for urging the extension of an observational programme in a remote part of the world. Other features in which 1959 differed from previous years were noticeable in both surface and upper air climatic sequences.

Recording of surface ozone was continued using a new electrolytic detector element designed by Dr. A. W. Brewer, of the Clarendon Laboratory, Oxford. It replaced the transmogrifier system[6] previously in use. There appeared to be good continuity between the two systems, the change-over taking place in March. Monthly means reached a clear maximum in winter and minimum in summer. In 1958, a secondary decrease which occurred at mid-winter[4] is attributed to the concentration of local contaminants beneath intense surface inversions. The 1959 apparatus was installed at the new site for the spectrophotometer, well clear of smoke from the main living hut. This work was carried out by J. A. Smith.

Another meteorological project, attempted by D. W. S. Limbert, was the investigation of the significant parameters involved in the growth-rate of sea ice. Temperature profiles, in air and ice, and wind profiles were obtained together with density and salinity samples. Combined with other data on energy balance (for example, radiation fluxes) available from base records, these measurements should help to assess the rival merits of recent theoretical predictions.

Movement of the Ice Shelf

The most significant work of the year was the determination of the movement of the ice shelf, both by conventional and by less usual methods. Owing to the scatter in astronomical fixes caused by intense refraction, it has taken three years to establish the movement within reasonable limits. A provisional estimate, based on results for 1957 and 1959 only, gives a W.N.W. movement of about 600 yd. a year. Simultaneous azimuth observations made during the same period show an anti-clockwise twist of the ice shelf. The best fit of the available results gives annual rates of twist of about 18 min. of arc in 1957, diminishing gradually to 15 min. in 1959. The 1959 work was carried out by M. A. Sheret and myself in conjunction with the geomagnetic programme.

We also repeated the local magnetic survey made a year earlier by A. Blackie and J. MacDowall[7], of the International Geophysical Year party. This had shown a vertical force anomaly of several hundred gamma to the north-west of the base and close to the ice front. It was wondered whether movement of the ice shelf over such an anomaly could be detected as little as a year later. The pattern of eight stations covering an area of some 16 sq. km. was re-surveyed, again using a *B.M.Z.* magnetometer. The contours of the anomaly were fully confirmed, but it was immediately apparent that the ice shelf had moved forward, carrying the stake pattern with it, relative to the underlying anomaly. A fairly precise evaluation of the movement would require a closer spacing of the grid and a small closed loop in the magnetic contours. Nevertheless, a provisional analysis of the results (made independently of the astronomical determination) gives a W.N.W. movement of about 500 yd. a year. There is clearly a wide opportunity for the use of this simple and direct technique in areas where the magnetic topography is suitably convoluted. Though the attainable accuracy cannot compete with orthodox survey work, successive surveys could be carried out during brief summer visits.

In addition to the two methods so far described, D. W. S. Limbert fixed the position of two icebergs (which were thought to be grounded on the sea bed) by triangulation from a measured pattern of movement stakes. By repeating the survey after an interval of nine months and using the change in bearings from the icebergs, it was possible to derive a third estimate of the movement of the ice shelf. The provisional reduction of the results gives a westward movement of about 400 yd. a year. Simultaneous with the absolute translation and twist of the shelf, the pattern of movement stakes was observed to undergo deformation, with relative changes of 1 or 2 ft. in 1,000 yd. occurring within a year.

Glaciology

Measurements of snow accumulation were made against three different patterns of stakes: the standard box pattern for net monthly accumulation; a line pattern, nearer to base, for day-to-day ablation and accumulation; and two units (resembling goal posts) for studying the migration of sastrugi. It was noticeable that aggregate totals of accumulation from a given pattern of stakes would sometimes exceed and sometimes fall short of the corresponding totals from the other patterns. The differences were maintained for perhaps months at a time, and are thought to show evidence of the long-term migration of shallow, large-scale features on the ice shelf. Measurements of density and sub-surface temperature profiles were also made. The work was carried out by D. W. S. Limbert.

Other Geophysical Activities

The geomagnetic programme was maintained by M. A. Sheret and myself. Because of the continual rise of the snow surface, the fixed mark could no longer be seen from the declinometer in the magnetic hut. The problem was solved by building a new declinometer room above the north porch which could be entered from below through a small hatch. The fixed mark could then be viewed above the snow-level. To ensure continuity of reference azimuth the angular difference between the old and new sites was determined by theodolite from the mark. Settling of the foundations of the magnetographs required regular adjustments to be made to the variometers but caused no undue difficulty.

A further aspect of the movement of the ice shelf is that the annual means of the magnetic elements, which normally yield the secular variation of the Earth's field, will include an additional term due to the movement of the magnetic hut relative to the magnetic topography of the sea bed. This spurious component can be allowed for when the movement and the contours of the isomagnetics are both accurately known. In addition to the local magnetic survey, the opportunity was taken to obtain measurements of vertical force during the course of a 33-mile physiological sledging trip to the east-north-east of the base. This work was done by Dr. J. N. Norman and G. M. Artz. When combined, the two surveys show that a complex system of magnetic contours covers the whole region so far explored. We can be reasonably certain that there is a corresponding complexity in the underlying geological structure, but it now seems improbable that anything can be deduced about the physical contours of the sea bed. Soundings made from the Falkland Islands Dependency Survey relief ship, R.R.S. *John Biscoe*, indicate that the ice shelf is floating in the area of Halley Bay and that their are no significant shallows which might account for the coastal features of the ice front.

The auroral physics programme was continued with quarter-hourly visual observations, and all-sky camera records during significant displays. M. A. Sheret, who carried out the work, is also attempting to investigate auroral–geomagnetic relationships. An investigation of tidal currents off the coast, made by me, was a continuation of a programme sponsored by the National Institute of Oceanography. The potential difference created by the motion of sea water across the Earth's magnetic field was detected by a pair of silver/silver chloride electrodes suspended below the sea ice near the bay[8]. Tidal variations can be distinguished in the records during periods when geomagnetic activity is slight. Seismological records were also continued until the end of the year.

Biology

Two distinct programmes were carried out by Dr. J. N. Norman. A physiological investigation into the micro-climate of individuals was sponsored by the Medical Research Council. Integrated skin temperatures were obtained, by means of vests sensitive to temperature worn next to the skin, for four subjects going about their normal duties. Additional readings were taken during the man-haul sledging trip already referred to, and these were linked with observations on dehydration and energy balance of individuals.

A separate investigation in the field of penguin biology was carried out during the winter months. By building a small satellite base with living hut and mobile generator, planned by G. R. Lush, it was possible to observe the vast Emperor penguin rookery (3 miles to the west of base) from close quarters. As a result, J. N. Norman, helped by M. A. Sheret, was able to collect a timed series of embryos and to extend our knowledge of the breeding cycle of these primitive creatures.

An attempt has been made to describe something of the scope and variety of the work now being carried out by the Falkland Islands Dependencies Survey at Halley Bay, with particular emphasis on the less routine aspects. We are indebted to the International Geophysical Year parties of 1956–58 for the excellent start given to the station. This article is published with the permission of the Director, Falkland Islands Dependencies Survey.

SPECIFIC INHIBITORS OF THE ADRENAL CORTEX

By Prof. J. H. U. BROWN

Department of Physiology, Emory University, Atlanta, Georgia

THE endocrine system is composed of many glands in often inaccessible locations with a wealth of interrelationships. In order to investigate the individual hormones it is necessary to remove the gland, or to inhibit in some way its function. Removal is often difficult and in many cases impossible. For this reason, one of the aims of endocrinology has been the development of substances which specifically inhibit a single endocrine organ.

It has been possible for many years to block the action of two of the endocrine glands with specific inhibitors. The use of alloxan to destroy the beta cells of the islets of Langerhans in the pancreas and thus produce true diabetes mellitus has permitted great strides in the study of the action of insulin. The use of the various thiouracils to inhibit synthesis of thyroid hormones and permit investigation of thyroid physiology is too well known to require discussion. The search for specific inhibitors of the other endocrine glands has, in general, been disappointing.

The use of a specific inhibitor for the adrenal cortex would be of special value to the endocrinologist since in most species it is impossible to remove the cortex without simultaneously removing the medulla, and since the presence of accessory glands in all species often makes the operation complicated. Furthermore, a substance which would inhibit specific pathways of steroid synthesis would be of inestimable value in elucidating the synthesis of the various steroids.

Amphenone *B*

Great interest was aroused in 1950 when Hertz, Allen and Tullner[21] reported that a new compound, *p*-aminopropiophenone (amphenone *B*) (Fig. 1), synthesized by Allen and Corwin[1] appeared to cause enlargement of the adrenal and thyroids of rats. Two explanations were possible: the pituitary could be directly stimulated to increase output of its hormones and thus stimulate the target organ to greater function, or secondly, the target organ itself might be affected by the drug. Administration of adrenal or thyroid hormones with the amphenone completely prevented the enlargement of the glands and indicated the site of action to be at the end-organ level. The results also suggested inhibition rather than stimulation of the adrenal and thyroid and demonstrated that the enlargement was due to compensatory hypertrophy which usually occurs in the absence of the target organ hormone consequent to the increased output of trophic hormones of the pituitary[23].

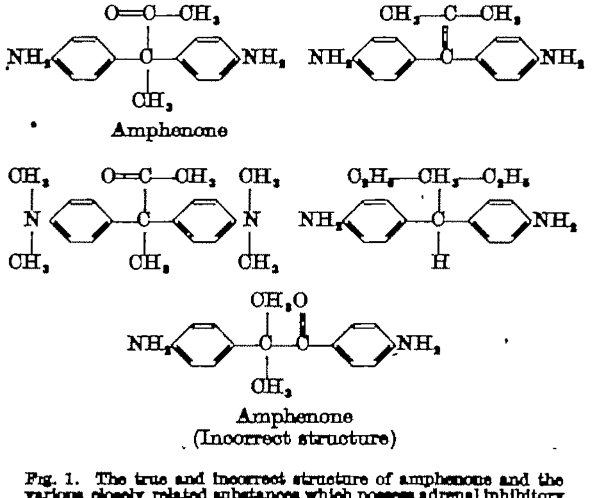

Fig. 1. The true and incorrect structure of amphenone and the various closely related substances which possess adrenal inhibitory action

The results were soon confirmed by Chappel *et al.*[12], by Coste *et al.*[15] and by Danowski[16], who reported finding increased numbers of basophils in the pituitary, increased lipid deposits in the adrenals, loss of colloid and increased epithelial cell height of the thyroid cells, and fatty infiltration of the liver of rats treated with amphenone. The results taken as a whole indicated decreased function of the thyroid and adrenal with increased output of pituitary trophic hormone.

The picture was apparently clear-cut until Hogness[24], Heming[26] and Vogt[31] presented results suggesting stimulation rather than inhibition of the thyroids and adrenals as a result of administration of amphenone. Vogt cannulated the adrenal vein and demonstrated increased steroid production when amphenone was given to rats. In the light of later experiments on both man and other animals, these results must be interpreted as due to peculiarities of dosage, to strain differences, or to unknown factors.

Despite the contradictory information, other experiments sustained the interest in amphenone *B*. For example, several workers[19,21,45] demonstrated that amphenone inhibited the production of aldosterone by the adrenal cortex at a much lower dosage than that required to suppress the output of the other adrenal steroids.

In view of the promise of amphenone as an adrenal cortical inhibitor attention was turned to the production of derivatives which might prove to be more effective or less toxic. Hertz[24] found that of some 25 derivatives only 3 had promise as inhibitors (Fig. 1). It should be emphasized that the structures reported by Allen and Corwin[1] and utilized by Hertz were not correct. In 1957, Bencze[14] found that the molecule became re-arranged (Fig. 1), so it is possible that other derivatives might prove more satisfactory theoretically than those based on the old structure.

Investigation was also proceeding on the mode of action of amphenone. Marks[29] reported that the drug appeared to inhibit pathways of steroid metabolism which did not require oxygen, that is, glands treated with amphenone to complete inhibition of steroid synthesis still utilized the same or greater amounts of oxygen. Marks also found that cholesterol accumulated in the adrenals of rats treated with amphenone and he suggested that the site of inhibition might be at the level of conversion of cholesterol to the precursors of the adrenal steroids (pregnenolone, for example). Rosenfeld and Bascom[64], in a much more elaborate study, utilized the newer methods of steroid identification and found that amphenone inhibited the 11, 17 and 21-hydroxylation of pregnenolone and probably inhibited the conversion of the 3-hydroxyl to a 3-ketone.

The demonstration of the action of amphenone in animals led to its immediate use in human patients suffering from adrenal cancer or hyperadrenalism. The drug was tried with several patients having adrenal carcinoma[25,34,38] with successful results. In these patients there was a decreased excretion of 17-ketosteroids, some evidence of tumour regression, and a depression in the excretion of 17-hydroxycorticoids. The experimental results had shown evidence of thyroid blockade as well as an adrenal action and a series of papers[34,69,73] demonstrated that iodine-uptake was depressed, organic binding of iodine was markedly decreased, and that enlargement of the thyroid occurred in man treated with amphenone. The drug was also tried in patients with hyperadrenalism[48,62,73,76] with considerable success as measured by regression of symptomatology.

However, difficulties soon arose in the use of amphenone. Patients developed thyroid blockade, toxic symptoms including blood dyscrasias, liver damage and general malaise. A major symptom was extreme drowsiness[34], which could be predicted from the anaesthetic property of the drug previously reported in rats[38]. It soon became obvious that the many disadvantages might outweigh the advantages of the drug.

DDD

At about the same time as the synthesis of amphenone, Nelson and Woodard[64] were testing the toxicity of insecticides, including the derivatives of diphenylethane. They reported that high doses of the material 1,1-dichloroethane, 2,2-*bis* parachlorophenyl (DDD) (Fig. 2) produced necrosis of the adrenal cortex in the dog. By contrast, DDT, the tri-chloroethane, was totally ineffective.

The compound was immediately taken up by Nichols and his co-workers[46–62], who found in short order that dogs fed DDD became insulin-sensitive, that the usual biphasic response of the blood sugar to alloxan did not occur in dogs treated with DDD, and that these animals did not respond to adrenocorticotrophic hormone injections with the usual increases in uric acid or allontoin excretion. Since all these responses are usually attributed to the metabolic activity of the glucocorticoids of the adrenal cortex an immediate presumption was made that DDD either suppressed the activity of the pituitary or of the adrenal cortex. Nichols[57] at first postulated that DDD blocked the effect of adrenocorticotrophic hormone on the adrenal, but was soon forced to the conclusion that DDD acted directly on the cortex.

Other evidence of the inhibition of the adrenal cortex was obtained by Little[48], who found that dogs fed DDD developed a depression of glomerular filtration-rate similar to that of adrenalectomized dogs, and by Nichols, Kaye and Larson[62], who found that DDD potentiated the action of barbiturates.

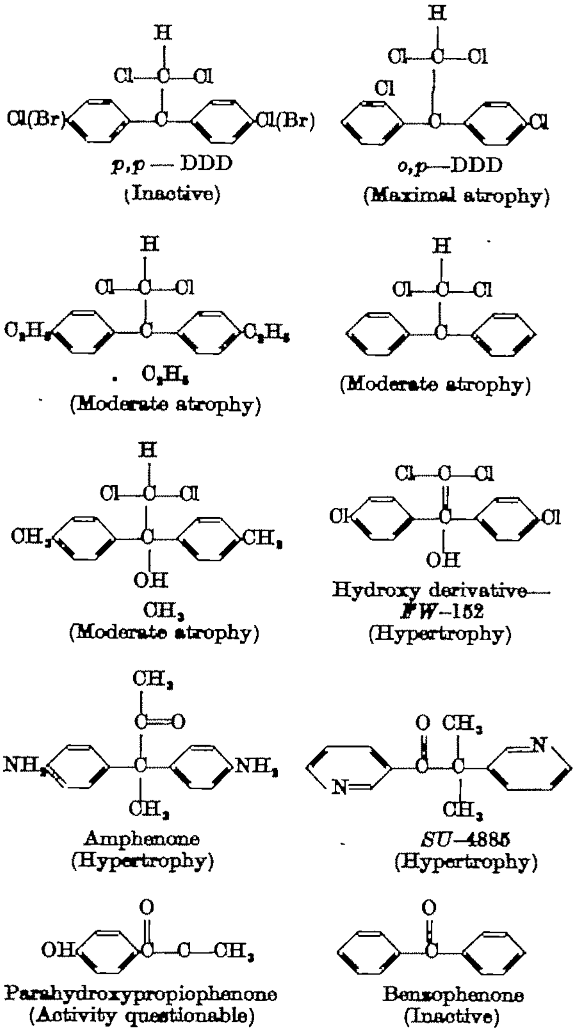

Fig. 2. Structures related to DDD with some indication of the activity as adrenal cortical inhibitors

The first direct proof of the adrenal suppressing activity of the substance was obtained by Brown *et al.*[9,10], who found that the excretion of 17-hydroxycorticoids was markedly depressed in dogs given DDD. They also reported that the effect could not be reversed by the administration of adrenocorticotrophic hormone, indicating the adrenal site of action, but that the effect could be completely reversed by the administration of cortisone. The results were soon confirmed by Kuchmeister *et al.*[45] and by Vilar and Tullner[79].

The action of DDD in the dog was clear. Identical results were obtained in cattle[56] and in the domestic fowl[55]. Unfortunately, the results were not so clear in the rat. Brown[6,7] found that DDD had some influence (decrease) on the eosinophil response of the rat to adrenocorticotrophic hormone and that it may have alleviated the course of alloxan diabetes in the same animal. Verne and Wegmann[77,78] claimed that DDD produced adrenal cortical atrophy in the rat. This was in direct contradiction to Brown[6] and others, who reported hyperplasia of the adrenal in DDD treated rats. Stoner[71], Haag *et al.*[37] and D'Arcy[19] failed to find evidence of any effect of DDD on this animal. It would appear that the situation is unresolved, and that further work is necessary. Perhaps the isomers to be discussed below will provide a compound active on the rat adrenal. This is a problem which must be attacked since the rat is the most commonly used laboratory animal in the investigation of adrenal function. It may be an interesting coincidence that DDD appears to be most active in those species which secrete hydrocortisone as the major metabolic steroid and is inactive in the one animal tested to date (the rat) which does not secrete this steroid.

Because of the possible use of DDD as an adrenal blocking agent, many derivatives have been investigated (Fig. 2). The most active of these is 'Perthane', the di-ethyl derivative of DDD. The drug is an active adrenocorticolytic agent, but appears to be active only at about three times the dose required for DDD[3,4,14]. The relationship between structure and function is somewhat obscure. Many derivatives have some activity and result in atrophy of the cortex, but there are several in the series which appear to produce hyperplasia of the adrenal[14,44]. It is not known if these later compounds act in a manner similar to that of amphenone, which they closely resemble in structure.

It is known that the action of DDD and amphenone on the adrenal cortex are not similar. Nichols and Hennigar[46] fed amphenone to animals previously treated with DDD, and DDD to animals previously treated with amphenone. They found that amphenone could not prevent the atrophy from DDD, but that the usual hypertrophy due to amphenone could be entirely prevented by DDD.

In addition to the more direct measurements of adrenal function under the influence of DDD (steroid excretion, etc.) there are more subtle indications that the gluco-corticoids are either not being produced or not active at the tissue-level. Candela and Candela[11], for example, found that the diaphragms of DDD-treated rats were insulin-sensitive when compared to normal diaphragms, while Nichols, Davis and Green[54] found that the adrenal cortices of dogs treated with DDD did not respond to adrenocorticotrophic hormone with the usual increase in oxygen consumption found with normal glands. Naidoff *et al.*[58] found that DDD lowered the blood-sugar of diabetic rabbits, and Tornblom[74] reported that DDD lowered the serum polysaccharides of the same species. All these observations suggest responses of the peripheral tissues similar to those obtained in adrenalectomy.

In course of investigations on DDD, many workers had noted that the dosage required to produce a given response appeared to vary from batch to batch of the technical material[8]. Conflicting reports were obtained from laboratories using different batches of DDD. These difficulties were resolved in 1958 when Cueto and Brown[16,17] reported the isolation from the technical material of an active agent which gave consistent responses at much lower dose-levels than that reported for the crude DDD. Characterization of the pure substance led to the conclusion that it was present to the extent of about 10 per cent in the technical products and was the *o,p*-isomer of DDD. The remainder of the technical material was largely *p,p*-isomer.

It was soon demonstrated that the *p,p*-isomer was inactive and that the *o,p*-isomer contained all the activity attributed to DDD. This explained many inconsistencies. Several groups had recrystallized DDD before using it and this effectively removed the active component. Others had used the technical material, and as the active isomer varied from batch to batch, inconsistencies were reported. At about the same time as the isolation of the active agent, Nichols[61] found that an oil isolated from the technical material was active in producing atrophy of the adrenals, but he failed to characterize the material. It was probably the *o,p*-isomer. Vilar and Tulner[79], however, used crystalline *o,p*-DDD and confirmed the results completely.

With the availability of a pure product, it became possible to test the material in man. 'Perthane' had been previously tested[64,78], but large doses were required and some toxicity developed. Sheehan and Nichols had previously tested DDD in man with negative results[70], but they had used the technical material with unknown amounts of *o,p*-isomer. Zimmerman[82], on the other hand, also used technical material and found some tumour regression occurred in cancer patients and that a modest decrease in blood corticosteroids could be elicited with the drug. Brown *et al.*[9] found a definite decrease in blood corticoids in three cancer patients treated with the *o,p*-isomer and Bergenstal, Lipsett, Moy and Hertz[3] found definite suppression of adrenal function in twelve patients with adrenal carcinoma with regression of tumours and objective improvement of the cancer. Some toxicity was reported. Tornblom[75] found that DDD decreased the incidence of hyaline vascular disease in diabetic man and noted that diabetics given the drug required a smaller insulin maintenance dose than before treatment.

To the present very little attempt has been made to determine the site of action of DDD on the adrenal cortex. Large doses of the drug cause necrosis with a complete disappearance of cell structure, but it is known that small doses will inhibit steroid production before signs of necrosis develops. Nichols was able to demonstrate an effect of DDD on the oxygen consumption of adrenals treated with adrenocorticotrophic hormone[54], but he did not attempt to determine the site at which the inhibition occurred. Because of its value as an adrenocorticolytic agent, further work should be done on this phase of the problem. It is also possible that use of the *o,p*-isomer or of some other derivative might make the compound effective in the rat and increase its value immensely.

SU-4885

In 1958, Chart *et al.*[13] reported that a new analogue of amphenone, designated as *SU*-4885 (Fig. 2), was effective in suppressing the adrenal function of dogs, rats and guinea pigs. The drug produced an increase in adrenal-weight, increased insulin sensitivity of experimental animals, had no effect on the thyroid, and was effective in suppressing steroid synthesis in adrenal slices.

Jenkins, Meakin, Nelson and Thorn[40] tried *SU*-4885 in man and obtained a decrease of 90 per cent in steroid excretion. The precursors of the 11-hydroxylated steroids appeared in the urine, indicating blockade of this step. The blockade was confirmed by the finding of large amounts of tetrahydro *E* and *F*. Similar results were reported almost at once by Liddle *et al.*[47]. In a later paper, Jenkins *et al.*[41] again reported almost total suppression of glucosteroid production by the adrenal under *SU*-4885 treatment and suggested that the major difference between *SU*-4885 and amphenone was that amphenone was less selective in action.

The drug has not yet been investigated to the extent which will allow prediction of future use in clinical medicine.

Other Substances

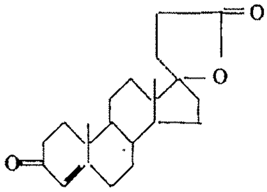
Several other materials have been reported to exert an inhibitory or lytic effect on the adrenal cortex. Dimethylaminoantipyrine and some of its analogues have been reported by Borth[5] to inhibit steroid output of the cortex. The effect is slight and the large doses required do not permit routine use.

Edgren *et al.*[20] found that 6-methyl-17-acetoxy-progesterone decreased adrenal size and function as measured by the 'cold' test. This is inconclusive evidence and no further work has been reported.

Inhibition of aldosterone secretion upon administration of delta-4-cholesterone has been reported by Frederickson[23] and Golden and Overman[26] reported necrosis of the adrenal cortex following infection with *C. diphtheria* in monkeys. The compound para-hydroxypropiophenone (PHP), which is essentially half the amphenone molecule (Fig. 2), has been tested by several groups. Foglia[22] reported that PHP caused a decrease in adrenal weights in rats, Sachsse[67] found improvement of diabetes upon treatment with PHP which might be attributed to decreased adrenal function and a consequent decrease in gluconeogenesis, while Danowski[18] found that the drug decreased adrenal size. In all cases, the effects were not marked and high doses were required.

Steroidal Lactones

A good deal of attention has been directed to a class of drugs which antagonize aldosterone and deoxycorticosterone (Fig. 3). The drug has been extensively investigated by Kagawa[33,34]. The effects are not mediated through the adrenal, and so this drug cannot be classed with those which have a direct adrenal action.



Spiralactone

Fig. 3. The structure of a steroidal lactone with effects on steroid excretion

Structure-function Relationships

All the compounds which are potent adrenal inhibitors appear to possess two six-membered rings linked together by one or two carbon chains. In the case of amphenone and of DDD phenyl groups are attached to the same carbon atom, while in the case of *SU*-4885, they are attached to adjacent carbon atoms.

The effect of substitution on function is not clear. The presence of substitutions on the phenyl rings is not necessary for activity (Fig. 2)[44], but substitution appears to enhance the activity in some cases. The addition of ethyl, methyl, chlorine and bromine to the phenyl group produces a more active compound. The use of nitro, methoxy, or aldehyde substitutions produces a completely inactive compound[4]. The effect of location of the substitution has not been extensively investigated. It is known that the *p,p*-chloro derivative is completely inactive while the *o,p*-chloro derivative is active in a high degree. Compounds are now being synthesized with various steric configurations to investigate this problem.

The substitution on the carbon adjacent to the phenyl attachments is important. A tri-chloro substitution (DDT) is completely ineffective, as is the mono-chloro compound[44]. Removal of the chlorines from the adjacent carbon, substitution of a hydroxyl group on the phenyl carbon, and apparently the presence of a ketone on one of the chain carbons results in hypertrophy rather than atrophy, although a greater or lesser inhibition of action may occur. Apparently more than one carbon must be present in the chain since benzophenone is inactive[73]. In this connexion it is interesting to note that a compound of related structure (3,5-dioxo-1,2-diphenyl, 4-*n*-butyl pyrazolidine) has been reported to have slight adrenal inhibitory activity[5].

It is interesting to note that all the compounds which have inhibiting properties appear to have a six-membered ring, but there appears to be no requirement that it be benzenoid in character. The nitrogen-containing ring of *SU*-4885 appears to be quite effective. Although the active amphenones mentioned by Hertz[30] all contained *p,p*-amino groups on the benzene rings, it is not known whether these are essential to activity. Reasoning from the information available on DDD one could conclude that other substitutions might be equally or more effective.

This work was supported by grants from the National Institutes of Health, National Cancer Institute (*Cy*-3150).

OBITUARIES

Dr. W. Lawrence Balls, C.M.G., C.B.E., F.R.S.

Dr. Lawrence Balls, who died on July 18, was the foremost of many workers who have been engaged on the development of Egyptian cotton during the present century. His personal investigations have been of great practical importance as well as of outstanding scientific interest. In addition to providing scientific knowledge, he markedly influenced the administrative procedures in Egypt for making that knowledge effective.

William Lawrence Balls was born in 1882. After being educated at King Edward VI School, Norwich, and St. John's College, Cambridge (of which he was a Fellow from 1909 until 1913), he became botanist to the Khedivial Agricultural Society in 1904 and served that body and (later) the Egyptian Department (later Ministry) of Agriculture until his retirement in 1947, except for a period 1915–26, when he was designer and head of the Experimental Department of the (then) Fine Cotton Spinners' Association, Ltd., at Bollington, Cheshire.

During the first phase of his career in Egypt, Balls made detailed physiological studies of the growth of the cotton plant and of the mode of development of the fibres produced from the seeds—the raw cotton of commerce. Many of the results of these fundamental investigations are summarized in his now classical works "The Cotton Plant in Egypt" (1912) and "The Development and Properties of Raw Cotton" (1915). He also made some of the earliest critical genetical studies of plant characteristics and features of fibre quality, and rapidly formed the conclusion that mediocrity and degeneration in both yield and quality were inevitable under Egyptian conditions unless genetic variability was minimized and controlled. From this arose his concept of 'pure line' strains. This work led to the development of methods for making available pure-line seed supplies. During his later career in Egypt, as chairman of the Cotton Research Board of the Ministry of Agriculture, Balls gave continuous encouragement to the policy of crossing and re-crossing of the various strains to exploit to the full the latent characteristics inherent in Egyptian cotton and persisting from the original historical medley of impure cottons.

From the start of his career, Balls was actively interested in the physiological requirements of the cotton plant, and this led him to study the water and drainage requirements for optimum yield under Egyptian irrigated conditions, with the results described in "The Yield of a Crop" (1953). In this work he arrived at the valuable, though possibly depressing, conclusion that the improvements in crop yield made over the years, by himself and his co-workers through better pest control, improved manuring, the development of more prolific strains, etc., had only made it possible to counterbalance approximately the progressive losses caused by the water-logging of the soil associated with the increase in the water-table following the change from the basin type of irrigation to perennial irrigation.

In considering fibre quality, Balls took as his end-point the quality of the spun yarn, and this interest, together with the circumstances of his career, led him into spinning technology. His "Handbook of Spinning Tests for Cotton Growers" (1920) was a pioneer work that needs little amendment to-day. His "Studies of Quality in Cotton" (1928), based on research work done at Bollington and describing notably the 'drafting wave' and the 'Rule' spinning frame, has influenced much of later technological research and development.

Balls was active to the end, and it was a pleasure to delegates at the Jubilee Conference of the Textile Institute (which had awarded him an honorary fellowship in 1943) in May of this year, to hear from the master himself a paper on the "Beginnings of Botany on a Cotton Crop".

Dr. Lawrence Balls was a great man, in the true sense of the words, who made for himself a career and won by his ability international recognition in a little-known and, at that time, little-regarded field of investigation.

D. W. HILL

Prof. J. Bronte Gatenby

PROF. JAMES BRONTË GATENBY, the eminent cytologist, died on July 20 while on holiday at Galway, Ireland. Born in 1892 in New Zealand, he developed a keen interest in entomology and this led him to correspond with Prof. E. B. Poulton in Oxford, where he later went as a student and studied under Prof. E. S. Goodrich. His interest in entomology was reflected in many of his later papers. He graduated in 1916 with first-class honours and was appointed lecturer in histology in Prof. (later Sir Charles) Sherrington's Physiology Laboratory. He soon became interested in cytology, particularly in the inclusions of the germ cells of a wide variety of animals, and he published a long series of papers on this subject. In 1918 he was appointed to a senior demyship at Magdalen College, Oxford, and in 1919 lecturer in cytology in the University of London, where he worked with Prof. J. P. Hill. During these years he produced a considerable number of papers on the embryology, oogenesis and spermatogenesis of both invertebrates and vertebrates. His D.Phil. he obtained from Oxford and his D.Sc. from London.

In 1921 he was appointed to the chair of zoology and comparative anatomy in Trinity College, Dublin, a post which he held until 1959, when he was appointed to a research chair of cytology in the same University. During this period in Dublin he attracted students from all over the world, and he was involved in several fierce controversies relating to the Golgi apparatus—the cell inclusion which he studied in considerable detail. These controversies were mainly concerned with Parat's vacuome hypothesis and also with the question of whether or not the Golgi bodies in many cells were staining artefacts.

Since the Second World War, Gatenby took an increasing interest in electron microscopy. He became firmly convinced of the great potentialities of this technique two years ago when he worked for a while at the Argonne National Laboratory in the United States. He was, however, always insistent on linking this work with light microscope studies. This was his second visit to the United States—in 1930 he spent a year at Yale University as a Seessel Fellow. In 1933 he was appointed visiting lecturer to the University of Louvain.

He had a very extensive knowledge of microscopical techniques, and for many years was a joint editor of "The Microtomist's Vade Mecum". He was on the editorial board of the *Journal of the Royal Microscopical Society* and other learned journals, and was made an honorary member of a number of scientific societies.

To his students Gatenby appeared rather fearsome at times, but to keen and interested ones he gave every encouragement and showed much kindness. He would stand for no sham or bluff. He was in many ways an outstanding representative of the old school of classical zoologists. His teaching and published work reflected his respect and affection for some of the great names of British zoology whom he knew well—Goodrich and Lankester in particular. By his death the world of cytology and zoology has lost an eminent man. He is survived by his second wife and four children by his first marriage.

J. N. R. GRAINGER

Prof. F. A. Jenkins

PROF. FRANCIS A. JENKINS, professor of physics in the University of California, died at his home in Berkeley on August 3, after an illness of two months. He was a graduate of the Universities of Chicago and Toulouse and had been a faculty member at Berkeley for thirty-one years. He had held Guggenheim fellowships at Utrecht, Uppsala and most recently at Oxford, where his presence and activity in the autumn of 1958 are warmly remembered at the Clarendon Laboratory, at Brasenose College, which made him a member, and by many friends and colleagues.

Jenkins's name is perhaps most widely known through the excellent text-book on optics, by Jenkins and White; but it is his research work, covering a wide field of optics and especially spectroscopy, which has established his reputation among physicists, chemists and astronomers everywhere. His chief contributions were in the field of molecular spectroscopy; of the numerous topics only some of the most important can be mentioned here: his thorough study of the CN bands and of perturbation effects in their rotational structure, the investigation of isotope effects and the determination of isotopic mass ratios (Li_2, BO), his work on the intensity distribution in the rotational structure of bands and on the changes of coupling conditions as the result of increasing rate of rotation (NO), the determination of nuclear spins and nuclear statistics from alternating intensities (Se, C^{14}) and the study of Rydberg series in band spectra.

In the field of atomic spectroscopy, his work on the quadratic Zeeman effect in sodium and potassium, of Zeeman effects in forbidden lines and on hyperfine structure and isotope shift is outstanding. He also made valuable contributions to spectroscopic methods, especially in the field of dielectric multi-layers, studying the performance of broad-band interference filters, the dispersion of the phase change in such filters and the ultra-violet reflectivity of multi-layers containing antimonous oxide and lead chloride. It was especially his knowledge and experience in this field from which the spectroscopy group in the Clarendon Laboratory derived great benefit during his stay there.

His most recent interests were exciton absorption spectra and methods of applying electronic computers to the analysis of band spectra. In the latter field he worked in close collaboration with the Departments of Chemistry and of Astronomy in Berkeley.

A feature common to all Prof. Jenkins's publications is their thoroughness and completeness, both in the measurements themselves and in their theoretical evaluation; there was no room for false claims, either in his work or in his personality.

Those who knew personally 'Pan', as he was called, will have lively memories of his warm personality, his human understanding and friendliness, his sense of humour and the breadth of his interests and concerns. Many will also recall his happy home and family, that meant so much to him. He was strongly attached to California, where he had spent most of his life, and he liked the camping holidays for which that State offers so many opportunities. But he also had strong ties with the Old World and felt very much at home in England and other European countries. His presence and contributions will be sadly missed at many spectroscopic conferences.

H. G. Kuhn

Prof. Tadeusz Miłobedzki

Prof. Tadeusz Miłobedzki, formerly of the Warsaw Polytechnic, died on July 13, 1959. He led a simple, quiet life and worked successfully until old age. He was a man of great intellectual power, a skilful research worker and an excellent teacher.

Miłobedzki was born at Koło upon Warta on June 16, 1873, and graduated at the University of Warsaw in 1897. He took a special interest in organic chemistry, and was a student of Prof. Wagner, a specialist in terpenes. He also worked in Berlin, Leipzig and Graz, and obtained his Ph.D. at the Jagellonian University in Cracow in 1918.

In 1906, when the Russian authorities had allowed the opening of the Polish Technical College, Miłobedzki was appointed a lecturer in inorganic and analytic chemistry there. In 1915 he took an active part in the organization of Polish university education. He was a co-organizer of the Warsaw Polytechnic and the first dean of its Faculty of Chemistry. In 1917 he was appointed an extraordinary professor at the Central School of Agriculture in Warsaw, where he became the first rector. In 1922 he was called to the chair of inorganic chemistry in the University of Poznań, and in 1929, after the death of Prof. J. Zawidzki, he succeeded to the chair of inorganic chemistry at the Warsaw Polytechnic.

For his outstanding work as a scientist, organizer and teacher, he was made an honorary professor of the Central School of Agriculture at Warsaw and of the Jagellonian University.

In 1922 Prof. T. Miłobedzki became an ordinary member of the Poznań Society of the Friends of Sciences, and in 1932 he was elected to the Warsaw Scientific Society. During 1937–39 he took part in the work of the Polish Committee of the International Union of Pure and Applied Chemistry. In 1945 he became a member of the Polish Academy of Science and Arts and, on its foundation, of the Polish Academy of Science.

Prof. Miłobedzki played a prominent part in the development of the Polish Chemical Society. In 1920 he was one of its founders and in 1928 he was elected president. During 1916–17 he was the editor of *Chemik Polski* and during 1935–39 he was the editor of *Roczniki Chemii* (*Annales Societatis Chimicae Polonorum*).

Prof. Miłobedzki and his pupils carried out important investigations on titration analysis. He also worked on phosphorus compounds, using not only the methods of classical inorganic chemistry but also those of physical chemistry, including the Raman spectra and absorption spectrometry. Prof. Miłobedzki also worked out a commonly applied new method for the detection of acid radicals. His books on analytical chemistry, "Szkoła analizy jakościowej" (School of Qualitative Analysis) and "Szkoła analizy ilościowej" (School of Quantitative Analysis), were much used.

Wiktor Wawrzyczek

NEWS and VIEWS

National Institute of Medical Research: Prof. P. B. Medawar, C.B.E., F.R.S.

Prof. P. B. Medawar, professor of zoology at University College, London, who is to succeed Sir Charles Harington in 1962 as director of the National Institute of Medical Research at Mill Hill, brings to the post an outstanding record in medical research and an exceptionally broad background of relevant biology. A product of the Oxford Department of Zoology and Comparative Anatomy, he began research in Sir Howard Florey's department with a study of growth and movement in cell populations. When the Second World War came, he turned to nerve regeneration with Prof. J. Z. Young's group, and the problems of nerve grafting soon led him to skin grafting. Ever since, though there have been many interesting by-products of his active mind concerning human growth, wound-healing, ageing and cell transformation, he has pursued the problems of the homograft reaction, tenaciously and resourcefully. He has immensely clarified this field, and has been the leading figure in an international movement which is contributing fundamentally to knowledge of immune mechanisms. His success in research has been due to an unusual range of gifts: skill and speed in the laboratory, a flair for the design of crucial experiments, and a powerfully analytical mind. He was elected to the Royal Society at an unusually early age in 1949, and received a Royal Medal in 1959. His work is communicated in an irresistibly brilliant style, and his powers of exposition have often been used effectively to a wider public, most recently in the Reith Lectures. Somehow he has combined his activity in creative science with a great amount of work in scientific policy-making, notably on the University Grants Committee (1955–60) and the Agricultural Research Council (since 1952). His ability to combine productive research with heavy administration assures the success of his new appointment.

The London Research Station of the Gas Council: Dr. R. H. Griffith

DR. R. H. GRIFFITH, director of research at the London Research Station of the Gas Council, has retired. Dr. Griffith went to Magdalen College, Oxford, and obtained a D.Phil. in 1925. In the same year he joined the research laboratory of the Gas Light and Coke Company. During the ensuing thirty-five years, Dr. Griffith has built up a world-wide reputation in the intricate field of catalysis, and has contributed a number of important papers on various aspects of this subject, notably in the *Proceedings* of the Royal Society. He is the author of a standard text-book on "Contact Catalysis" and also of "The Practice of Research", which describes in detail the functions, structure and organization of a chemical research department attached to industry. In 1945 he was appointed senior research chemist to the Gas Light and Coke Company, a position he continued to hold with the North Thames Gas Board after nationalization. On the retirement of Dr. Hollings in 1952, Dr. Griffith was appointed controller of research of the Board and director of the London Research Station of the Gas Council. Dr. Griffith has been awarded the H. E. Jones Medal of the Institution of Gas Engineers on two occasions. The Gas Council is now to review its research activities, and for the time being Mr. G. U. Hopton, senior research chemist, will be responsible for research at the Fulham Laboratories of the London Research Station.

Hector: a New Research Reactor

THE United Kingdom Atomic Energy Authority has now issued the contracts for the construction of a new zero-energy oscillator reactor which is to be built at the Atomic Energy Establishment, Winfrith. The reactor, which will be called *Hector* (heated experimental carbon (graphite) thermal oscillator reactor), has been designed expressly to facilitate the use of the pile oscillator technique for evaluating the nuclear behaviour of fuels, moderators, and structural materials in reactors. This technique, which utilizes small samples, has been devised by the Authority to further the reactor physics aspects of power reactor development. It is expected that *Hector* will go critical during 1962. The reactor possesses a unique feature, in that it is possible to reproduce closely the conditions appropriate to many different designs of power reactors. The reactor core is an annulus of graphite and highly enriched uranium/aluminium alloy within which various assemblies of fuel and moderator may be constructed around a central tube. The sample under investigation will be cycled through this tube, producing oscillations in reactor power-level from which the nuclear behaviour of the sample, under the conditions reproduced by the assembly, can be determined. Since the fuel material in the assembly may be natural or enriched uranium-235, plutonium, thorium, uranium-233 or irradiated elements from power stations, and since the assembly can be heated to 450° C., it is possible to investigate samples under the conditions to be found throughout the life of many different designs of power reactors. Successful measurements are possible only if the temperature of the heated assembly is extremely stable. It is desirable that the moderator temperature should not change by more than 3×10^{-3} degree C. per minute. The design of the reactor to achieve this has involved the use of novel techniques, specialized materials and the highest standard of control and instrumentation.

Special Assistance for Effluent Liaison

A THREE-YEAR project to assist tanners and dressers with effluent problems has just been started by the British Leather Manufacturers' Research Association. The project has been made possible by the agreement of the leather industry, through the United Tanners' Federation and the British Leather Federation, to contribute 'new' industrial income for 'effluent liaison'. To this the Department of Scientific and Industrial Research will add £2 for every £1 of 'new' income up to a maximum of two-thirds of the total cost (estimated to be about £20,000 for the three-year period). The terms on which the grant has been awarded are that the industrial income must be additional to any other income which the British Leather Manufacturers' Research Association receives, and that it must be used for liaison purposes only. It was decided that under this scheme, two new liaison officers, one a specialist in vegetable tanning, the other a specialist in chrome tanning, should be appointed to recommend and demonstrate to supporting firms modifications in leather-making processes designed to reduce effluent problems. A mobile laboratory will be equipped to undertake the analytical tests required in this work.

British National Lending Library for Science and Technology

CHANGES in the book-buying policy of the National Central Library recently adopted by the Trustees, partly in consequence of the creation of a new National Lending Library for Science and Technology, are described by Mr. S. P. L. Filon, librarian and secretary to the Trustees, in an article contributed to the *Library Association Record* for August. More attention will be devoted to earlier British books (before 1958), particularly those published since 1800, when they are actually required and not available. Many foreign books not available in Britain will in future be bought, rather than depend on foreign loans. Books in English, published in other countries and in the Commonwealth, will remain a substantial proportion of those purchased by the Library, and generally the same conditions as for British books will be applied. Consideration of the purchase of medical books has been deferred until the policy of the National Lending Library for Science and Technology in this respect is clarified, and acquisition of research material, both books and periodicals, in the field of science and technology has been mostly left to the future National Lending Library. The Library will acquire foreign university theses if these are not available in Britain. In future, the Library will acquire all current British Government publications as well as useful older publications and certain publications of international bodies obtainable through H.M. Stationery Office. In future, priority will be given to the acquisition of publications of learned societies, both British and foreign. As regards periodicals, it is expected that virtually every periodical in science and technology will be taken by the National Lending Library for Science and Technology, or by some library in association with it. The position in the humanities will be very different, and while the Trustees envisage that the National Committee on Library Co-operation may wish to organize a scheme for coverage of British periodicals, they have authorized the librarian to acquire foreign periodicals where these are not available and where they are not more suitably taken and made available by another library. The policy regarding acquisition of periodicals for loan will be closely related to that for the purchase of learned society publications. It is also intended to build up a collection of specimen copies of new periodicals. Mr. Filon stresses that these changes imply no changes in the rules for the inter-lending work of the Library or in its work for adult classes.

Index Chemicus

A NEW journal entitled *Index Chemicus* has been published by the Institute for Scientific Information, 1122 Spring Garden Street, Philadelphia (annual subscription rates: educational foundations, 250 dollars; industrial and Government agencies, etc., 500 dollars). The publication is a monthly index of new compounds reported in the literature and claims to give information within thirty days of its first appearance. The first number reports more than 3,700 newly synthesized organic compounds. The production is in the hands of a staff of experienced organic chemists, and the preparation uses both manual and machine methods for handling chemical information. A system of checking to ensure accuracy is in use. The text lists chemical names, structural diagrams and molecular formulæ, as well as complete bibliographical information including article title, authors' institutions, addresses, and original journal references for each compound. Indexes will be issued quarterly and annually. Each entry is numbered and there is an inserted author index referring to these numbers. It is noticed that Japanese and Russian literature is extensively covered.

There is no doubt that this new publication will greatly facilitate the work of research chemists in the field of organic chemistry. In other abstract journals there is a serious time lag between the publication of the material and the appearance of the abstract, and particularly in the publication of indexes. The amount of information which can be extracted from the *Index* is, however, very limited, but enough is probably given to enable a chemist to know if the publication listed is likely to be of interest to him. Particulars of prices, etc., also a booklet and specimen pages, can be obtained from the Institute.

Nuclear Engineering Abstracts

THE appearance of yet another abstracting journal is an event which it is natural to regard with some suspicion. However, the practice of nuclear engineering involves the drawing together of so many different sciences that there has been a growing need for a journal which attempts to cover the whole field. *Nuclear Engineering Abstracts* sets out to provide informative abstracts of all the important publications which are relevant to the theory or practice of nuclear engineering; the coverage is wider than that of many abstracting journals, since newspapers and house journals are included, when appropriate, in addition to the usual periodicals, patents and reports. The standard set by the first issue of the new journal is high; the layout is good, so also are the indexing and cross-referencing. If this standard can be maintained in succeeding issues, *Nuclear Engineering Abstracts* will be essential reading for anyone taking a real interest in the field (*Nuclear Engineering Abstracts*, 1, No. 1; July 1960. Pp. 100. London: Silver End Documentary Publications, Ltd., 1960. Annual subscription covering four issues, post paid, £6 6*s.*; 18.50 dollars. Single copies, if available, post paid, £1 12*s.* 6*d.*; 4.75 dollars).

Scientific Papers of the Meteorological Office

"Airborne Measurements of Latitudinal Variation of Frost-point Temperature and Wind" is the subject of the first number of a new series entitled "Scientific Papers" to be published by the Meteorological Office (Air Ministry: Meteorological Office. Scientific Paper No. 1. Pp. ii+30. (M.O. 664.) (London: H.M. Stationery Office, 1960.) 3*s.* 6*d.* net). This series replaces the former "Professional Notes" and "Meteorological Reports", and like them each number will contain one paper. It will give accounts of research work carried out in the Office. It is printed on paper more than an inch wider than its predecessors in order to allow more space for the diagrams which are an important feature of most meteorological papers. Accounts of the most important investigations will, however, continue to appear in the "Geophysical Memoirs" series. This first issue, by N. C. Helliwell, summarizes and discusses observations of the elements quoted made by the Meteorological Research Flight in the lower stratosphere on six days in the summer of 1956 and three in March 1957 between Minorca and the Norwegian Sea near the Arctic Circle. The frost-point, giving a measure of the humidity, showed little variation with latitude. Jet streams were traversed on some flights, and the horizontal wind-shear in them was measured. Clear-air turbulence was, as expected, encountered in association with some jet streams, but it was also encountered at places where no explanation for it could be found. The temperature observations on two flights were such as to suggest that tropospheric fronts were continued into the stratosphere.

Environment and Culture in Southern Rhodesia

ROGER SUMMERS, curator of the Museum at Bulawayo, Southern Rhodesia, has published an interesting paper on the relationships of environment to past cultures in that country (*Proc. Amer. Phil. Soc.*, 104, No. 3; June 15, 1960). In arguing from the present to the past, changes in climate naturally have to be remembered, but the physical map and the geology of the region have remained constant. No less than twenty-three distribution maps are given, showing such things as the modern vegetation pattern and what it would be with various percentages of the present rainfall. Other maps show the distribution of the prehistoric cultures, as well as of the rock-shelter art and the ancient mine workings. Why did some early cultures shun areas where Mopane forests would be growing? The answer is probably because the tsetse fly *Glossina morsitans* would have made cattle breeding impossible in those districts. The various possible invasion routes depend to a large extent on the 'lay-out' of the country, and peoples coming in from outside have, of course, greatly influenced past history. Actually, Southern Rhodesia can be shown to have been both a cradle and a corridor. Again and again not enough attention has been paid to the relationship of various culture groups to their environment, both climatic and geological, when the past history of a country is being studied. Roger Summers is to be congratulated in having so successfully followed in the footsteps of Sir Cyril Fox in producing for Southern Rhodesia what Sir Cyril did in his "Personality of Britain".

Strontium-90 and Natural Strontium in Human Bone

A RECENT report, "Radioactive and Natural Strontium in Human Bone", from the Chemistry Division of the Atomic Energy Research Establishment, Harwell, is the latest in the series in which results of the analyses of human bones in the United Kingdom for strontium-90 and natural strontium are listed (A.E.R.E. *R*23246. By J. W. Arden, F. J. Bryant, E. H. Henderson, G. D. Lloyd and A. G. Morton. Pp. 8. London: H.M. Stationery Office, 1960. 1*s*. 9*d*. net). The results given are for samples received during 1959 and analysed by the end of the year. Many of the samples were from subjects who died during 1957 and 1958. For the determination of strontium-90 the separation and counting of the yttrium-90 daughter is the preferred method, but when the activity is too low the determination has to depend on counting of the strontium source. Emission spectroscopy was used for the determination of the natural strontium sources. The results show that between the latter part of 1958 and the first half of 1959 there was a rise, compared with previous periods, in the number of strontium units absorbed for all the various age groups except the 'over 20 years' group. The contamination of diet in the United Kingdom is largely dependent on the rate of fall-out and the higher bone burdens thus reflect the increased rate of deposition which has occurred since early 1958.

Low-temperature Fuel Cell

THE successful development of a low-temperature fuel cell that can generate 3–5 times more power per unit volume than other similar cells has been announced by the Shell Research Centre at Thornton, Cheshire. The high output has been achieved as a result of fundamental studies on fuel cell electrodes. This work has led to the development of inexpensive, highly active electrodes. The cell can operate with either alkaline or acid electrolytes. When run on hydrogen and oxygen at a pressure of 3 lb. per sq. in., current densities of 70 amp. per sq. ft. can readily be obtained with both types of electrolyte at room temperature. If air is substituted for oxygen there is little loss in performance. As the cell warms up to 60° C., the output is doubled and a power output of 3–5 kW. per cu. ft. is achieved. Multiple fuel cells with up to six cells per inch have been constructed, and it is considered that units with a power-to-weight ratio of 50 W. per pound could be made. The work at Thornton is continuing and will include a study of fuels other than hydrogen. During the past decade, much of the effort on fuel cells has been devoted to the development of high-temperature cells since, in these cells, the electrode reactions are rapid and high efficiencies can be more easily achieved. Recently, however, more attention has been given to low-temperature cells and it would appear that this is a fruitful field for further research and development.

Travelling Fellowships in Medicine

APPLICATIONS are invited for Rockefeller travelling fellowships, Sir Henry Wellcome travelling fellowships, U.S. Public Health fellowships and the French exchange scholarships. These awards are open to graduates in science who are resident in the United Kingdom and have some training in research in medical science and who intend to return to Britain to resume or take up new appointments in university, hospital or academic research. Fellowships held in the United States provide annual maintenance allowance at rates varying from 3,000 dollars according to individual circumstances (500–700 new francs monthly with additional sterling marriage allowance in the case of French exchange scholarships) and travelling expenses are also provided. Further information and application forms may be obtained from the Secretary, Medical Research Council, 38 Old Queen Street, London, S.W.1, and the closing date for applications is October 31.

Announcements

MR. A. R. O. WILLIAMS, a managing director of Consolidated Gold Fields, Ltd., and of New Consolidated Gold Fields, Ltd., has been elected president of the Institution of Mining and Metallurgy for 1961–62. He has served on the council of the Institute for fifteen years, and held the office of vice-president during the period 1951–54.

DR. W. J. KROLL, of Corvallis, Oregon, will deliver the sixth Castner Memorial Lecture, "The Fusion Electrolysis of Titanium", on October 7 at the Royal College of Science and Technology, Glasgow, C.1. Further information can be obtained from the Society of Chemical Industry, 14 Belgrave Square, London, S.W.1.

THE Research Laboratories of the Timber Development Association at St. John's Road, Tylers Green, Penn, Buckinghamshire, are holding two open days on October 12 and 13. Further information can be obtained from the Association's headquarters, 21 College Hill, London, E.C.4.

THERE will be open days at the National Chemical Laboratory, Teddington, Middlesex, on October 19 and 20. Applications for invitations should be sent to the Director not later than September 24. Those already on the mailing list for invitations need not re-apply.

THE next meeting of the Biochemical Society will be held in the Department of Biochemistry, the University of Glasgow, during September 29–30, and will include a colloquium entitled "The Biosynthesis of Nucleic Acids". Further information can be obtained from Dr. F. A. Robinson, c/o Allen and Hanburys Ltd., Bethnal Green, London, E.2.

JOINT Conferences are to be held on "Analytical Chemistry in Nuclear Reactor Technology" and "Nuclear Reactor Chemistry" at the Civic Auditorium, Gatlinburg, Tennessee, during October 12–14. The Conferences are sponsored by the Analytical and Reactor Chemistry Divisions of the Oak Ridge National Laboratory. Further information can be obtained from C. D. Susano, Oak Ridge National Laboratory, P.O. Box Y, Oak Ridge, Tennessee.

THE Aero Space Medical Panel of the NATO Advisory Group for Aeronautical Research and Development (AGARD) will hold its sixteenth meeting in Istanbul, Turkey, during October 3–8. Technical papers on clinical aviation and space medicine will be presented. Further information can be obtained from the Advisory Group for Aeronautical Research and Development, Organisation du Traité de l'Atlantique Nord, 64 rue de Varenne, Paris 7ème.

ERRATUM. In the article entitled "Blue Hazes in the Atmosphere" by Dr. F. W. Went, in *Nature* of August 20, p. 641, the sizes of particles mentioned are incorrectly given in 'mμ'; they should be 'microns'.

WEATHER PROBLEMS IN AGRICULTURE

FOUR papers were presented during the second morning (July 1) of the summer meeting of the Royal Meteorological Society at Queen's College, Dundee.

Introducing the session before presenting the first paper, Dr. H. L. Penman, of Rothamsted Experimental Station, stated that two of the main objectives of crop-weather studies are, first, to achieve better growth of healthy plants, and secondly, to exercise control of pests and diseases the activity of which is dependent on weather. It is essential for the agricultural meteorologist to know something of the principles of plant-growth, though two of his problems can be derived from the simple equation for photosynthesis of carbohydrate. The need for short-wave radiation made a study of solar radiation income imperative, both as physics and as climatology. The latter topic was taken up later by Mr. G. J. Day. The supply of carbon dioxide to the crop can now be treated as a meteorological phenomenon similar to heat and vapour transfer (see second paper, by Dr. J. L. Monteith), and out of it there arises a third problem. The physiological state of the plant that permits easiest uptake of carbon dioxide also provides the most favourable conditions for transpiration, and this transfer of water from soil to atmosphere presents the meteorologist with another flux problem, and with a problem in energy balance. To the micro-meteorologist it brings problems concerned with the source of the water, and the effects that it has on the immediate environment of the plant, that is, on the 'weather' experienced by the plant, its pests and its pathogens.

In the hope that the information would some day be biologically useful, Dr. Penman and Mr. I. F. Long have been collecting detailed physical measurements in various farm crops. "Weather in Wheat"[1] is a condensation of the results for three summers of temperature, humidity and wind-speed, all continuously recorded over and within the crop on a site on which many other auxiliary measurements were made. Selecting a few topics, primarily of meteorological interest, a demonstration of variability across the site at constant height provides one of the reasons for using long-period averages in the analysis of profiles. Hot spots and damp spots can persist for several hours. By plotting wind-speed against temperature, and against vapour pressure, at the four observation heights above the crop, straight lines were obtained, from which it was inferred that the aerodynamic transport constants were effectively equal for transfer of momentum, sensible heat and latent heat. Computation of the transfer of latent heat for the forty-eight 4-hr. periods in eight days of fine weather gave very good agreement with the measured values from a large transpiration gauge, continuously weighed, in phase, amplitude and in mean daily total. Both estimated and measured values showed that transpiration is a daylight phenomenon. Calculations were presented for two periods to show how the transpiration stream was built up, layer by layer, between the soil surface and the top of the crop. It seemed that all layers contributed about equally (in this particular crop). Some time in the future it may be possible to tackle the carbon dioxide problem in the same way and find out the vertical distribution of efficiency of assimilation.

Dr. J. L. Monteith, also from Rothamsted, then summarized what he and Mr. G. Szeicz had done in measuring "The Carbon Dioxide Flux over a Field of Sugar Beet"[2], work first made possible by a grant from the Rockefeller Foundation and later by the skill of the Infra-Red Development Co. in building an instrument capable of measuring to 0·1 p.p.m. of carbon dioxide. From differences of concentration at two heights 25 cm. apart above the crop, and contemporary wind data, fluxes were computed. For a period of a few weeks from August onward the flux was always downward in daylight (assimilation > respiration), the main changes following very closely behind those of solar radiation intensity. The night flux was upward, at a fairly constant rate representing plant respiration and biological action in the soil. Net growth over the period calculated from these physical measurements agreed well with direct measures by crop sampling. Later, in October, biological activity in the soil appeared to provide more than enough carbon dioxide for plant growth—the day-time flux was upward except during short sunny intervals around noon, and the crop was still growing. Though this latter behaviour raised some important problems in soil microbiology, Dr. Monteith confined his discussion to the meteorological aspects of the earlier period, giving a hint that he had since made progress in the interpretation of the interactions of radiation intensity, mixing parameters and carbon dioxide uptake, and that there was a possibility of a link-up between the field-work he and Szeicz were doing, and laboratory work on single leaves being done elsewhere. As a purely meteorological point, he suggested that the uniform upward flux at night might be exploited in the study of transfer processes in very stable conditions. In discussion, the somewhat optimistic suggestion was made that this physical technique might replace periodic sampling, to give a non-destructive method of measuring the rate of plant growth.

Although there are many stations with long records of duration of bright sunshine (n), it is only within the last few years that there has been any attempt to measure incoming solar radiation (Q) at stations in Britain other than in south-east England. There has been much use of an empirical equation $Q/Q_A = a + bn/N$, in which Q_A is the radiation that would reach the site in the absence of an atmosphere, and N is the maximum possible duration of sunshine. Under the title "Radiation Climatology", Mr. G. J. Day (Meteorological Office, Eskdalemuir) first gave the values of a and b he has derived from monthly mean values of Q/day and n/day obtained at twelve stations having records of Q for at least three years. The geographical distribution of stations was very irregular, with large gaps in northern Scotland, eastern Scotland, eastern England, the Welsh border and along the south coast. Mr. Day made reservations about the accuracy of some of the radiation records, but by giving equal weight to all observations he found that a has a range from 0·08 to 0·19; and b varies from 0·63 to 0·95. Neither constant shows any systematic geographical variation. Having got local values of a and b from short-period records, he applied them to large neighbouring areas with long-term records of n, to derive expected mean monthly average values of Q. These were plotted together with the corresponding values given by Black[3] for twenty-eight stations in the area bounded by lat. 50–60° N., long. 5–30° E., and isopleths of mean monthly radiation drawn for north-west Europe using the two sets of estimates. The value of the twelve maps lies in their detail, and this may be modified after a re-check of some of the basic data. When published, they will be a very useful supplement to the corresponding maps of rainfall, temperature and sunshine.

During recent years there has grown a demand for more information about the effects of shelter on plants and on animals. Much of the resulting field work has the active co-operation of the Meteorological Office in Edinburgh, and in a paper entitled "Wind-breaks—Some Physical Effects", Dr. R. W. Gloyne of that Office considered some purely aerodynamic aspects of air flow over a barrier. Summarizing world experience, he listed the three distinct flow regions that arise: (1) the up-wind boundary layer; (2) the down-wind disturbed region; and (3), overlying these, the undisturbed flow. The disturbed region can be subdivided into: (2*a*) a space, immediately behind the obstacle where there may be strong eddies—it is here where it is most difficult to reconcile field and wind-tunnel studies; (2*b*) a region, farther down-wind, of turbulent motion, approximately conforming to a logarithmic profile, which, with distance, becomes in fact the logarithmic profile of the original undisturbed flow. The sizes of the regions (as multiples of the barrier height h) vary with the permeability (φ) of the barrier. In brief (with winds of normal incidence): for dense barriers ($\varphi < 40$ per cent) the original profile is re-established at about $30h$, though a logarithmic profile may re-appear at $20h$, and the original mean direction is re-established at about $15h$. For open barriers ($\varphi > 60$ per cent) the re-establishment of speed profiles is much as for dense barriers, but that of mean direction occurs much nearer the barrier, perhaps as close as $2\frac{1}{2}h$ behind a very open mesh. The width of the affected area depends on the length (L) of the barrier. When $L > 20h$, the system behaves almost as a portion of an infinite barrier; a shorter barrier has relatively larger edge effects so that the affected area varies roughly as L^2, approximating to a parabola with its vertex perhaps $1\frac{1}{4}L$ down-wind.

Dr. Gloyne concluded with a brief reminder that there is a pressure excess up-wind and a pressure deficiency down-wind of an obstacle placed in an air stream, and he suggested that pressure measurements, similar to those made in wind tunnels, might be useful in wind-break studies.

TUBERCULOSIS IN ANIMALS

TUBERCULOSIS in animals was the subject of the fourth symposium of the Zoological Society of London, held on May 24. Mr. J. N. Ritchie, who organized the meeting, presided at the evening session. Dr. R. E. Glover was chairman at the morning session, and in the afternoon Dr. J. M. Ross filled this position.

Dr. Glover explained that the subject was appropriate for discussion at this particular time because of the progress that had been made in the eradication of tuberculosis from the cattle in Great Britain. With this advance, it was useful to review the position among other animals.

The first paper was by Dr. J. T. Stamp, who dealt with the comparative pathology. In calves, the incidence of tuberculosis is low, and infection enters mainly by inhalation or is congenital. Hæmatogenous dissemination is frequent. The fact that the incidence of tuberculosis increases considerably with age shows conclusively that tuberculosis of the adult is not merely a slow progression of lesions acquired in calfhood. In the older animals, the site of the primary complex is predominantly pulmonary and it is very obvious that advanced pulmonary tuberculosis develops as a result of bronchial dissemination following cavitation of the primary lung focus. The pathology of tuberculosis of the udder shows that there is always extensive involvement of the milk ducts.

In the pig, the chief route of infection is by the alimentary tract, and this gives rise to an incomplete primary complex in the regional lymph glands. In bovine-type infection in this species, hæmatogenous dissemination is common, but chronic pulmonary tuberculosis occurs only infrequently.

Horses have a high resistance to tuberculosis. Primary infection is almost entirely by ingestion. Hæmatogenous dissemination is frequent and gives rise either to miliary tuberculosis or to large tumour-like swellings, not unlike those of sarcoma.

The tuberculin test and the laboratory diagnosis of tuberculosis were discussed by I. W. Lesslie, who gave a brief history of the methods of preparation of tuberculin and the ways in which it had been used.

The general objective of research on tuberculin is to obtain a preparation which will give a maximum response in the infected animal at all stages of sensitization and a minimum response in the non-infected or non-specifically sensitized animal. He described the procedure necessary for the characterization of tuberculins.

The intradermal comparative tuberculin test has been developed for use in cattle. It consists in the injection of 0·1 ml. of avian and mammalian tuberculins in selected sites in the neck. The reaction at each site is measured, and the test is interpreted on each animal with reference to the results recorded in the whole herd and having regard to the herd history and clinical findings. *P.P.D.* tuberculin is used (mammalian 2·5 mgm./ml., avian 0·5 mgm./ml.). The relative strength of the *P.P.D.* tuberculins resulted from somewhat empirical decisions based on the strength of the tuberculins formerly used in this test.

A laboratory service is of great value in confirming field diagnosis and, particularly, for typing the organisms concerned. Frequently, when re-infection in a herd of cattle is being investigated, the knowledge of the type of organism involved is helpful in tracing the source of infection, both in animals and in man.

Mr. J. D. Blaxland, in describing tuberculosis in poultry, said that it is no longer of great importance as a cause of serious loss in our flocks. This relates generally to the lower age of birds being kept and the better conditions of husbandry. Nevertheless, tuberculosis still accounts for a fairly high proportion of condemnations of poultry carcasses. The disease affects domestic and wild birds. There is no good evidence that wild birds play any large part in infecting domestic species, but apparently wild birds do acquire infection from poultry. Wild birds may, however, be responsible for infecting farm animals.

Organisms of the avian type may cause progressive disease in pigs, and account for about one-third of the reports of tuberculosis in British pigs. Avian-type infection in cattle is important because it sensitizes the animal to tuberculin and, unless some form of comparative tuberculin test is used, may lead to errors in diagnosis.

Mr. I. M. Lauder, discussing tuberculosis in dogs and cats, mentioned that the incidence is much reduced. Bovine-type infection is now rare among cats, but a few cases of human-type infection occur. Tuberculosis was found in 1–2 per cent of autopsies of dogs in veterinary schools in Great Britain in the last five years. Infection in dogs is mainly of human-type and a source in man has been found in 77 per cent of cases, usually within the household. Symptoms in dogs are readily recognizable, and in these animals diagnosis may be made by X-ray examination. The tuberculin test is not reliable but a test using B.C.G. vaccine intradermally is of some value. Many of the comparatively few cases of tuberculosis found in dogs are 'open' and humans might therefore be infected from this source.

In a paper on the disease in zoo animals, Mr. Oliver Graham-Jones emphasized that the primates are very susceptible, and it is common in all vertebrate species. All three main types of the organism are involved. Many carnivores, which might be expected to acquire bovine tuberculosis from eating infected meat, instead are found to be infected with a human strain apparently from close contact with the general public.

Bovine infection has been recorded in monkeys, although one would expect the infection to be with the human strain entirely.

There is considerable difficulty in diagnosis because the usual signs of loss of condition leading to emaciation are not so apparent in animals in captivity. The use of laboratory techniques in diagnosis is becoming more important; but it is recognized that a suitable diagnostic test is needed. The only test available at present is the intradermal tuberculin test, as developed for cattle. There is some promise, however, from the use of B.C.G. vaccine which was developed by the author as a diagnostic aid in primates and has since been used in dogs.

Treatment is, of course, possible; but it was stressed that eradication of the disease by destruction of the affected animal, and prevention of recurrence by strict measures of disinfection was the best practical course. Precautions have, of course, to be taken by testing incoming animals with tuberculin. So far as possible, this should be done before the animals leave their country of origin; but this is sometimes quite impracticable. Whatever the practical difficulties of carrying out tuberculin tests and eradicating the disease from zoo animals, it was most important to appreciate that in the light of the current successful eradication programme for tuberculosis in cattle, it is most undesirable that zoological gardens should remain a reservoir of infection which might overspill into rural areas.

Mr. R. V. Blamire, dealing with tuberculosis and food inspection, pointed out that although tuberculosis has, in the past, been regarded by food inspectors as the most important animal disease, its significance has rapidly declined in recent years in Great Britain. More than 97 per cent of milk consumed is now either heat-treated or comes from attested herds.

The techniques of meat inspection are exacting, and the judgment of tuberculous carcases is often difficult.

In 1957, approximately 7·3 per cent cattle, 0·1 per cent calves, 3·6 per cent pigs, and 0·0006 per cent sheep were found to be affected with tuberculosis when inspected in abattoirs in England and Wales. In 1950, it is estimated that the value of meat rejected because of tuberculosis was about £1,000,000; in 1955, although the price of meat had doubled, £800,000, and in 1957 it was £500,000. Soon, the loss should be negligible.

The risk to public health from the consumption of under-cooked tuberculous meat has never been clearly established; but it should not be under-estimated. The detection of tuberculosis by meat inspectors will in future have more animal health than public health significance. Differential diagnosis will then become very important.

The disease in man was dealt with by Prof. J. W. Crofton.

With the greater control of malaria, tuberculosis has become the world's most important public health problem. The World Health Organization calculates that 0·5–1 per cent of the entire population of the world is coughing up tubercle bacilli at any one time. Since the introduction of modern chemotherapy in 1947, there has been a dramatic fall in mortality from tuberculosis, at least in the economically developed countries; but the fall in notifications has been very much slower. Human infection by bovine tubercle bacilli can be measured directly only by typing bacilli isolated from patients. Indirect estimates can be made by following trends of tuberculosis in young children, who are likely to be infected from milk, or of such forms as abdominal tuberculosis which are likely also to be associated with milk infection. Figures quoted demonstrated such falls, greater in urban areas, where milk infection was first well controlled, than in rural areas, and much greater than the falls in respiratory tuberculosis.

The control of infection with human bacilli depends on efficient case-finding, mainly by mass miniature radiography, on efficient treatment to render patients permanently non-infectious, on efficient prophylactic vaccination with B.C.G. and on the general improvement in environmental conditions. Figures for Edinburgh were quoted to show the dramatic effect relatively thorough re-organization and good teamwork can have not only on the mortality but also on the morbidity of tuberculosis. It is suggested that, with sufficient energy and enthusiasm, the elimination of tuberculosis could be proceeding much more rapidly than it is in most areas at the present time.

Mr. W. D. Macrae traced the story of the eradication of tuberculosis from cattle from its beginning with the introduction of the Tuberculosis Attested Herds Schemes in 1935. It proved relatively easy to reduce an incidence of 20 per cent to 0·3 per cent; but there is real difficulty in reducing this figure any further for various reasons, such as re-infection from other animal sources, including man; loss of tuberculin reactivity at certain stages of the disease; and residual infection on farms, particularly in old, dilapidated buildings.

The overall current incidence of infection is 0·16 per cent of the animals tested but in some areas it is now as low as 0·05 per cent. Whether it will ever be reduced beyond this figure is a matter for conjecture.

Among the reactors disclosed, some 70 per cent show evidence of disease at postmortem examination in abattoirs. This figure of confirmation was higher at one stage but has fallen somewhat as a result of difficulties in carrying out adequate postmortem examinations and the apparent increase in the number of reactors showing no visible lesions.

In the course of dealing with bovine tuberculosis, the incidence in pigs of the bovine type infection has been markedly reduced and may well disappear in this species.

A great deal of effort is still required to maintain the disease under strict control. There must be regular organized tuberculin testing at appropriate intervals and tracing of animals which have been in contact with infection, so that the herds to which they have moved may be tested. Every source of information of the presence of tuberculosis in cattle must be used, including abattoirs and knackeries.

Tuberculosis in cattle, although not eradicated in a literal sense, is at least under satisfactory control, and there is every promise that it will be maintained at an extremely low incidence in future. Coincidentally, the amount of infection among other animals has been reduced in parallel, but certain precautions are still necessary to prevent re-infection of herds of cattle. Man may remain a source of infection, and while bovine-type tuberculosis in man is probably not sufficiently common among people who are in close contact with animals to make this a serious hazard, it has to be appreciated that as the interval between tests of herds is extended any source of re-infection is very important.

THE BRITISH GELATINE AND GLUE RESEARCH ASSOCIATION

THE nineteenth meeting of the Research Panel of the British Gelatine and Glue Research Association was held on May 19, with the chairman of the Association, Mr. S. G. Hudson (Richard Hodgson and Sons, Ltd.), in the chair.

Dr. G. R. Tristram (Department of Physiology and Biochemistry, University of St. Andrews) presented "A Preliminary Study of the Thermal Conversion of Acid-soluble Calf-skin Collagen into Gelatin". The collagen was obtained by extraction of calf-skin with cold aqueous acetic acid. The release of end-groups on heating with water at *p*H 6 was investigated, using Sanger's method. Changes in optical rotation and viscosity caused by heating at *p*H 3·3 in 0·1 *M* aqueous acetic acid solution were recorded. At *p*H 6, most of the collagen dissolved after 1 hr. at 50° C. and all of it after 1 hr. at 60° C. Solubilization was accompanied by a large increase in ε-amino groups reactive towards Sanger's reagent and by the appearance of terminal amino-groups of a similar pattern to those found in eucollagen by Courts[1]. End-groups were also estimated after keeping the collagen in strong aqueous urea at 15° C. so as to obtain a comparison with the effect of heating in water. On heating at *p*H 3·3 the optical rotation and viscosity rose to a maximum at about 28° C. and then fell. Dr. Tristram drew some tentative conclusions about the unmasking of N-terminal residues during the treatments applied and discussed the question of there being one or more chains in the collagen structure.

The second paper, "The Swelling of Gelatine Films", by Miss E. M. Simms and Mr. J. N. Blake (Richard Hodgson and Sons, Ltd.), was presented by Mr. Blake. A variety of gelatine gels and sols were dried on a solid supporting base at various temperatures in the range 5–60° C. The resultant thin films were detached and allowed to swell freely in water at 10° C.; previous workers in this field have studied attached films. The weights and dimensions of the swollen films were measured. By far the most important factor controlling swelling was the temperature at which the films were dried; for example, a 210*g*. Bloom acid-process pigskin gelatine film, imbibed twenty-three times its weight of water if dried at 5–10° C. but only six times if dried at 30–35° C. The imbibition was largely evidenced by an increase in thickness rather than in linear dimensions, whereas films dried from the sol state exhibited the opposite behaviour. Swelling in water at 20° C. was considerably greater than at 10° C. and swelling was more pronounced in films dried from weak (5 per cent) solution than from strong (20 per cent) solution. Films dried unrestrained on liquid surfaces from both sols and gels exhibited subsequent swelling of the sol form type. The extensive results were discussed in terms of the molecular orientation of the systems during drying.

Mr. A. M. Kragh (British Gelatine and Glue Research Association) gave the final paper, entitled "The Flocculation of Suspensions with Gelatine". Gelatines and animal glues have a flocculating action on a wide variety of suspended solids of which quartz has been most studied, and this property has been evaluated in comparison with that of other flocculating agents both polyionic (for example, synthetic polyamides) and non-ionic (for example, dextran). Gelatine flocculates best where almost all of it is adsorbed on to the particle surfaces and where the amount so adsorbed is about one-third of the maximum adsorbable. It is exceptional among flocculating agents in its ability to be strongly adsorbed on a wide range of different surfaces and in that its flocculating action is strongly dependent on *p*H. The lively discussion centred around the mechanism by which flocculation is induced in these systems.

DOMESTIC HEATING AND THERMAL INSULATION

DIGEST 133 of the Building Research Station, entitled "Domestic Heating and Thermal Insulation" (Pp. 7. London: H.M. Stationery Office, 1960. 4*d*.), brings together the essentials needed to guide the choice of the standard and methods of heating from among the many systems that are available. In choosing a domestic heating system the decisive questions are: What standard of heating is required? How much will it cost to run? Convenience in operation and the form of heat distribution preferred are also important.

Broadly, the systems of domestic heating can be divided into three main categories: (1) Full house warming. (2) Partial heating, that is, the full heating of two or three rooms from a central heat-source, with the remainder of the house heated as required by gas or electric fires: or the background warming of the whole house to a uniform temperature lower than that obtained by category (1) together with 'topping up' in individual rooms as required. (3) Heating limited to individual appliances in one or two of the main living rooms.

The main differences in the three standards of heating are in the scope of the heating service. In the full house-warming systems and background heating systems, for example, comfort is enhanced by the fact that the house is uniformly warm; such systems are essential for the open-house plan. By contrast, systems using separate appliances, for example, open fires, in a limited number of rooms give a less-uniform standard of comfort.

The standards covered by these three categories can be characterized broadly in terms of difference between the average outdoor temperature over the whole heating season and the average indoor temperatures they provide.

Assuming an average seasonal outdoor temperature of 43° F., a temperature difference of 18° F., averaged over 24 hr., can be taken as representative of full house warming, 13° F. for partial central heating systems and 11° F. or less for the third category. The smaller temperature difference between the medium and low standards of heating may be explained by the fact that even in dwellings where the bedrooms are unheated some stray heat is received from the heated part of the house. These average temperature differences can help in estimating seasonal fuel requirements and, therefore, running costs. They are not, however, appropriate for estimating maximum heat demands and hence the size of the heating plant; these have to be calculated from a maximum temperature difference between indoors and outdoors.

For a fair comparison of capital costs of various domestic heating systems, account should be taken of any building costs incidental to the heating installation, such as those of brick flues and fuel stores, or, conversely, the saving effected if these items are not required. For example, in a system comprising one open fire with back boiler, electric immersion heater for summer use and two electric fires, the cost of a chimney breast and flue and a fuel store for the open fire is about 25 per cent of the total cost of the installations. Broadly, the capital costs of the three categories of heating are in the same order as the standard of heating attained, but there may be some overlapping.

The seasonal heat loss for a particular dwelling will depend to some extent on the overall floor area, on the grade of insulation, the standard of heating, the ventilation-rate and the length of the heating season.

To estimate the seasonal fuel requirements the seasonal loss of heat should be divided by the calorific value of the fuel multiplied by the 'house efficiency' of the heating system.

Other points affecting the choice of a heating system are convenience in operation and the form of heat distribution. The size and number of heating appliances required for a particular heat service depend mainly on the maximum heat demand during a cold spell.

POPULATION TRENDS AMONG HAWKS AND OWLS IN ILLINOIS

DATA on hawks and owls in Illinois, as reported in the Christmas counts sponsored by the National Audubon Society and its parent organizations, have been analysed by Richard R. Graber and Jack S. Golden to determine population trends for the years 1903–55 (Biological Notes, No. 41. Dept. Registration and Education, State of Illinois).

Even though most of northern and central Illinois offered a fairly uniform habitat of cultivated farm land with relatively little forest, the distribution of raptors was not uniform, and raptor populations varied considerably even within relatively small areas. Highest concentration of raptors was in the southern part of the State. Through the years a given locality, in relation to other localities, has tended to show a consistent rank with regard to the density of its raptor populations.

Analysis of frequency of occurrence for all species of raptors in the period 1903–55 was based on 527 censuses—103 in southern, 123 in central, and 301 in northern Illinois. This analysis shows the expected higher frequency of prairie-inhabiting species of raptors in central and northern Illinois and of woodland species in southern Illinois. Regardless of habitat, certain species, such as the sparrow hawk and the marsh hawk, were seen with increasing frequency from north to south, as though responsive to a temperature cline.

The combined data for all raptor species show that there has been a marked and consistent decline in winter raptor populations during the period 1903–55. Peaks representing years of high populations are lower in later years. Trends in raptor populations were deduced from birds per observer-hour, birds per party-hour, and birds per mile.

The records of individual species show that the rough-legged hawk has suffered the severest decline in numbers; the red-tailed hawk, the sparrow hawk and the barred owl also decreased. Marsh hawk and the red-shouldered hawk populations have not changed appreciably. The bald eagle has been increasing in numbers since the early 1940's; but this is the only species for which a notable increase was shown. The records for many species are too incomplete to evaluate.

Because the decline in raptor populations is shown particularly among the less-wary species and those species that are most likely to be encountered by man, it is suggested that man may be directly responsible for the decline. This view is corroborated by the fact that many raptor band returns are from birds that were trapped or shot and also by the indication that a notably lethargic species, the rough-legged hawk, has suffered the severest decline.

The species of raptors, namely, *Buteo* spp., *Circus* spp. and *Falco sparverius*, which have been protected by law since 1919, were seen at least seven times as frequently as the previously unprotected accipiters and the great horned owl.

SINGAPORE BOTANIC GARDENS

A SPECIAL issue of the *Gardens' Bulletin* (17, Pt. 2; 1959. 12.50 dollars. Obtainable from the Botanic Gardens, Singapore) has been issued to commemorate the hundredth anniversary of the founding of these well-known gardens. In fact, a botanic garden was established in Singapore soon after its founding in 1819 by Sir Stamford Raffles, nutmegs, cloves and cocoa being among the early introductions. This garden was closed after some years in a retrenchment of expenditure, but new gardens, the present ones, were established on a new 60-acre site towards the end of 1859 (see also *Nature*, 184, 1602; 1959).

Since then the gardens have been extended and amplified and for many years have been recognized as being among the most important tropical institutions of this kind, the more so as they are set in a region of very considerable agricultural importance and quite exceptional floristic interest. Virtually from the outset, the staff have paid attention to the needs of practical agriculture and horticulture as well as to systematic and other aspects of scientific botany usually associated with botanic gardens. This was exemplified in a remarkable degree by the work of Dr. H. N. Ridley, director of the Gardens during 1888–1912, who has not only been rightly named "the father of Malaya's rubber industry" but was also responsible, as an indefatigable field botanist, for vast accessions of new plants to the gardens and its herbarium. After his retirement, he produced his five-volume work on the "Flora of the Malay Peninsula" (1922–25).

As several distinguished botanists have worked on the staff of the Singapore Botanic Gardens over the years, the output of work, often on plants of unusual scientific interest, has been both extensive and impressive. In the present commemorative volume (pp. 125–340) the reader will find much that is pertinent, informative and interesting. J. W. Purseglove has contributed a paper on the history, functions and contemporary work of the gardens; T. A. Russell has described the relationships between them and the Royal Botanic Gardens, Kew; while H. J. Lam has written of Singapore and Leyden. Other authors deal with the contribution which work in the gardens has made to agriculture in the Malaysian region, and there are several papers of both general and special interest by well-known botanists; for example, R. E. Holttum has written on his work on orchids, gingers and bamboos carried out in the gardens, and E. J. H. Corner has discussed the importance of the taxonomy of tropical plants in contemporary botany; and so on.

Perhaps the best way of indicating briefly the value of the present volume is simply to say that, for the general botanical reader, it affords an unusually interesting introduction to the many facets and fascinations of tropical botany.

ROAD ACCIDENTS DURING CHRISTMAS 1959

TWO factors stand out in the Road Research Laboratory report of the investigation of the 150 fatal road accidents in England and Wales during the Christmas period (December 24–27, 1959)—the bad weather conditions and the unusually high proportion of people involved in the accidents who had taken alcohol (Road Research Technical Paper. No. 49. Pp. iv + 20. Published for the Department of Scientific and Industrial Research by H.M. Stationery Office, 1960. 1*s*. 9*d*. net).

The investigation was carried out at the request of the Minister of Transport and shows that the number of fatalities per mile travelled by motor-vehicles was high on each of the four days of the Christmas period when compared with the other days in December or with the year as a whole.

The factors usually associated with road accidents (such as vehicle defects, cross-roads, and skidding on wet roads) were present in the normal proportion.

The weather conditions were bad. Roads were dry for only 10 per cent of the accidents; in 73 per cent it was dark and wet; in 12 per cent it was daylight and wet; and in 5 per cent it was icy. The report states: "this weather would be expected to result in increased accident frequency but not to the extent that occurred".

In at least 56 per cent of the accidents one or more of the people involved had taken alcohol not long before the accident. The corresponding figure in a normal period is 18 per cent. The report concludes: "the bad weather of the Christmas period made travelling conditions difficult. The fact that many of the people involved in the accidents had been drinking beverages containing alcohol would be expected—in the light of previous research—to have made many of them less able than usual to deal adequately with the difficult conditions. Although other factors may have been involved, the combination of these two alone might account for the high accident-rate over the period".

UPPER-ATMOSPHERE WIND STUDIES BY *SKYLARK* ROCKET SODIUM EXPERIMENT

By Dr. G. V. GROVES

Physics Department, University College, London

IN the sodium experiment, sodium vapour is ejected from a high-altitude rocket along its flight path. If the experiment is performed at twilight, when the sky has darkened yet the trail itself is still in sunlight, the trail glows conspicuously yellow by re-radiating the *D*-line emission from the Sun. This experiment, originally proposed by Prof. D. R. Bates, was first performed in 1955 at White Sands, and is now being carried out with the *Skylark* rocket at the Woomera Rocket Range.

The first *Skylark* experiment was carried out on December 3, 1958, the rocket being fired within 2 min. of a specified time, when the Sun was at a depression of 6° below the horizon. The sodium trail was laid continuously from 67 km. altitude over the trajectory vertex at 126 km., and down to a height of 93 km. Photocells on the rocket recorded sunlight from 60 km. altitude on the upward path to 69 km. on the downward path.

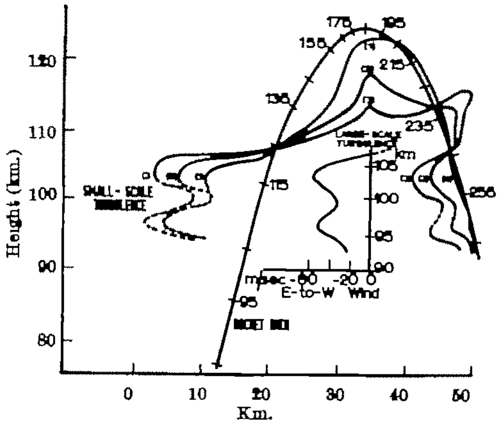

Fig. 1. East-to-west displacement of sodium trail. *Skylark* 11. Woomera, South Australia, December 3, 1958, 19.43 hr. Numbers on rocket path give time in sec. after launching. Sodium trail at (1) + 270 sec., (2) + 330 sec., (3) + 390 sec.

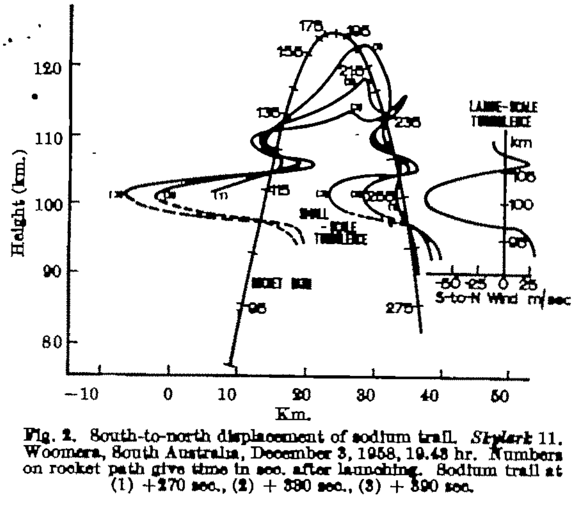

Fig. 2. South-to-north displacement of sodium trail. *Skylark* 11. Woomera, South Australia, December 3, 1958, 19.43 hr. Numbers on rocket path give time in sec. after launching. Sodium trail at (1) +270 sec., (2) + 330 sec., (3) + 390 sec.

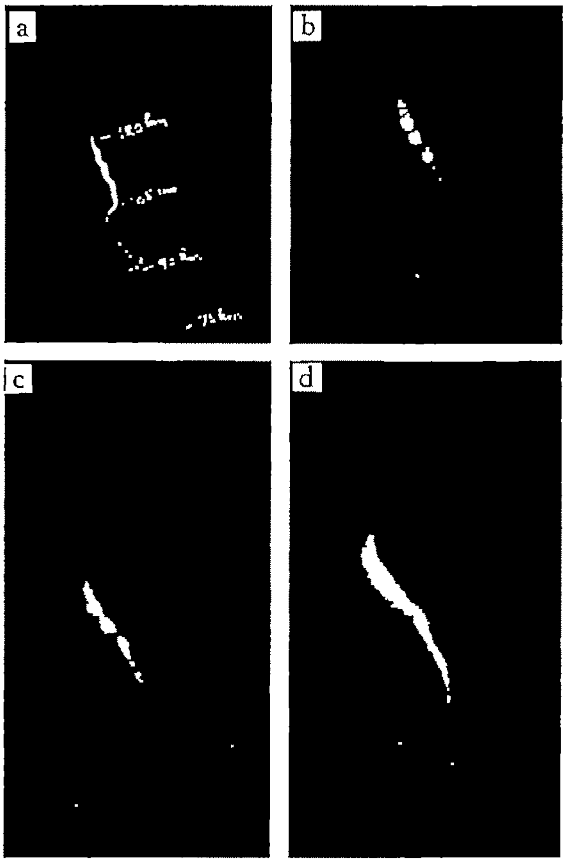

Fig. 3. *a*–*d*, Exposures of sodium trail made at 2½, 3½, 4½ and 5½ min. after launching

Photography of the trail was undertaken by twelve cameras of either moving-film or fixed-plate design, distributed between three roughly symmetrically placed observation posts. All cameras carried orange filters and were orientated in slightly different directions to increase sky coverage. Exposures were of 5-sec. duration, synchronized to within ¼ sec., and were made at intervals of either 1 or 5 min. The trail was bright enough to be recorded photographically for about 10 min., and persisted visually for about 20 min.

The series of photographs reproduced here were taken at 1-min. intervals from + 2½ to + 5½ min. from the time of launch, and the rocket is still in the field of view of the first three. The width of the sodium trail reaches a maximum near the vertex of the trajectory on account of the slower speed of the rocket and the lower ambient air density into which the vapour expands. The short waviness of the trail near the vertex is thought to arise from the rotation of the rocket as the wave-length corresponds closely to the measured spin. The main distortions of the trail arise from the wind structure, as the sodium atoms very quickly pick up the mean motion of the atmosphere at these heights.

The method of triangulating the trail depends on identifying corresponding features on various photographs taken from different camera posts. The identified points are then measured up in a plate-measuring machine, together with a number of star images as reference points. The processing of the data was carried out at the Admiralty Research Laboratory, Teddington, using the *Pegasus* computer. The accuracy of the triangulation depended on the width of the trail and on the presence of readily identifiable features. The width of the trail increased from about 1 km. at the lower heights to 3 km. at the vertex, and the standard deviation in the triangulation was usually less than half the width of the trail.

Fig. 1 shows the rocket trajectory and the sodium trail projected on the east–west vertical plane. The complete trail is plotted at + 4¼, + 5¼ and + 6¼ min. Fig. 2 shows the corresponding results for the south–north direction. The rocket trajectory was obtained optically using contraves, the data being supplied by W.R.E., Salisbury.

Figs. 1 and 2 show several interesting features. Small-scale turbulence appears to be present to a height of 102 km., while above this level, the trail remained unbroken. At the lower heights the trail broke up increasingly rapidly, and at 94 km. had disappeared within 2 min. Fig. 3*a* shows this part of the trail at about 1 min. after formation. From 94 to 102 km. the trail took some 8 min. to break up.

Below 107 km., the air motion is horizontal, and portions of the trail on both the upward and downward legs of the flight path are correspondingly displaced. The variation of wind speed with height is shown in Figs. 1 and 2 from 93 to 107 km. Above 107 km., the air appears to be moving in large cells with vertical motions of 50 and more m./sec. The cell size is difficult to estimate on the evidence of a single firing, as the trajectory intersects only a small part of the wind structure. The horizontal extent appears from Figs. 1 and 2 to amount to several tens of kilometres.

Acknowledgments are gratefully made to the Royal Aircraft Establishment for provision of the rocket and arranging its firing (particularly Dr. E. B. Dorling); to the Weapons Research Establishment, Australia, which carried out the firing and operated the cameras (particularly Mr. P. Moran and Mr. J. S. Colville); to Dr. E. B. Armstrong and Dr. J. Mazur, The Queen's University, Belfast, who prepared the first trial burners and carried out tests on them; and to the Mathematics Department, Admiralty Research Laboratory, Teddington (Miss M. Thorpe, Mrs. L. Blake) for triangulation computations on the sodium trail.

This work formed part of the programme of the British National Committee for the International Geophysical Year.

FATE OF TRANSFORMING DEOXYRIBONUCLEATE FOLLOWING FIXATION BY TRANSFORMABLE BACTERIA

I

By DR. MAURICE S. FOX and DR. ROLLIN D. HOTCHKISS

The Rockefeller Institute, New York

An analysis of the kinetics of the reaction between transforming deoxyribonucleate and transformable pneumococci has shown first a reversible adsorption of the deoxyribonucleate by the bacteria, followed by an irreversible fixation of the deoxyribonucleate[1]. Fixed deoxyribonucleate is defined as that which cannot be removed either by exhaustive washing or treatment with deoxyribonuclease. The quantity of such deoxyribonucleate fixed by the transformed population of bacteria is proportional to the number of bacteria transformed; and the efficiency with which such fixed deoxyribonucleate may yield a transformed bacterium is very high[2-4]. For preparations of the most active deoxyribonucleates less than two and perhaps one bacterial equivalent of donor deoxyribonucleate fixed by the recipient population yields a bacterium transformed with respect to a particular genetic property observed.

The experiments to be described represent an attempt to examine the growth of the transforming deoxyribonucleate following its fixation by transformable bacteria. Transforming deoxyribonucleate carrying both a biological label and a phosphorus-32 label has been introduced into transformable bacteria. After various times of incubation following the fixation of the labelled deoxyribonucleate, the total bacterial deoxyribonucleate from aliquots of the transformed population is isolated. This newly isolated deoxyribonucleate is used to transform a second bacterial population and the ratio of its biological activity to the amount of phosphorus-32 fixed by this new population is determined. An increase in the absolute quantity of the deoxyribonucleate capable of conferring the chosen property, as a consequence of synthesis of new deoxyribonucleate by the original transformed bacteria, results in a dilution of the phosphorus-32 label and therefore an increase in this ratio.

Transformable bacteria sensitive to streptomycin are incubated for 15–40 min. at 30° with the deoxyribonucleate labelled with phosphorus-32 isolated from bacteria resistant to streptomycin. Pancreatic deoxyribonuclease (20 μgm./ml.) is added and the mixture transferred to 37° C. The first sample is removed after 5 min., placed in an ice-bath, and further samples are removed at various times as the culture grows. An aliquot is removed to measure the quantity of phosphorus-32 incorporated and the culture is assayed after 2-hr. incubation for the total number of cells transformed, in this case from streptomycin-sensitivity to streptomycin-resistance.

After sampling for a bacterial count (viable and Petroff–Hausser), the iced aliquots are filtered, thoroughly washed and re-suspended in 0·15 *M* sodium chloride, containing 0·05 *M* sodium citrate and 4 mgm./ml. bovine serum albumin fraction V.

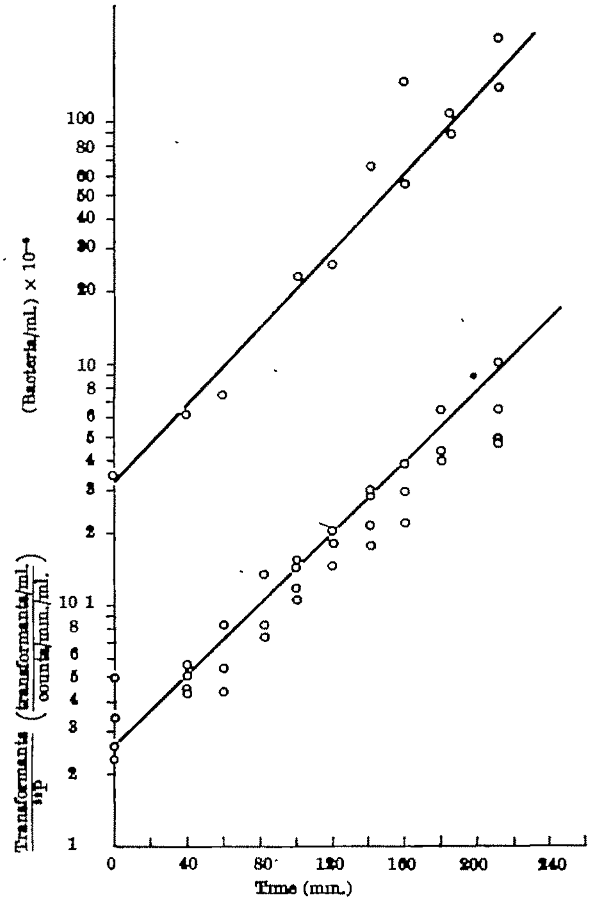

Fig. 1. Growth of bacteria, and dilution of phosphorus-32 of transforming deoxyribonucleate. Transformable bacteria were allowed 25 min. exposure to deoxyribonucleate at 30°. Deoxyribonuclease was added and bacteria were incubated at 37° C. for 5 min. prior to time zero

The re-suspended cells are lysed with sodium deoxycholate at 37° C. (5 min.), precipitated with 1·3 vol. of alcohol, centrifuged, and the crude deoxyribonucleate pellet dissolved in saline buffered with 0·01 *M* phosphate *p*H 7·8. Such solutions are used for transformation of a new culture of streptomycin-sensitive bacteria, measuring number of cells transformed and quantity of phosphorus-32 fixed.

The activity of this re-isolated deoxyribonucleate, when measured in terms of the yield of transformants per unit of phosphorus-32 fixed, is not changed significantly by passage through the bacteria if the deoxyribonucleate is re-isolated 5 min. after fixation (Table 1). In Table 1 are indicated the values of these activities before and after passage through transformable bacteria for a number of deoxyribonucleate preparations labelled with phosphorus-32 of various specific radioactivities. For deoxyribonucleate re-isolated after longer incubation and growth of the transformed bacteria, this activity increases as a function of time (Fig. 1). Also shown in Fig. 1 are the counts made in a Petroff–Hausser chamber of the number of bacteria per ml. The similarity of these two curves suggests that the transforming deoxyribonucleate, or material resembling the transforming deoxyribonucleate, increases at the same rate as do the bacteria in the total culture.

Table 1. RECOVERY OF PHOSPHORUS-32 LABELLED DEOXYRIBONUCLEATE (DNA) ACTIVITY FOLLOWING PASSAGE THROUGH TRANSFORMABLE BACTERIA

Duration of exposure to ^{32}P-labelled DNA	Transformants per unit of ^{32}P fixed for original DNA	Transformants per unit of ^{32}P fixed for DNA re-isolated after 5 min. incubation at 37° with DNase
36 min.	8	15
40 min.	6	5 4
25 min.	2·8	3 4
15 min.	100	104
15 min.	28	30

These data are insufficient to indicate whether or not it is possible to superimpose these two curves. In order to determine more precisely the relationship between these two growth-curves, the biological activity of the newly fixed deoxyribonucleate was directly compared with the biological activity of deoxyribonucleate resident in the recipient bacteria.

In a manner similar to that described above, transformable bacteria sensitive to streptomycin and resistant to *p*-nitrobenzoic acid (that is, 'wild type', see ref. 5) were exposed to deoxyribonucleate isolated from bacteria resistant to streptomycin and sensitive to *p*-nitrobenzoic acid. Thus, the deoxyribonucleate responsible for streptomycin-resistance was introduced into bacteria carrying resident deoxyribonucleate responsible for resistance to *p*-nitrobenzoic acid. The process of deoxyribonucleate fixation was terminated after 15 min. at 30° C. by the addition of deoxyribonuclease. The transformed population was transferred to 37° C., 5 min. allowed for action of deoxyribonuclease, and samples, were removed at various times thereafter. Deoxyribonucleate was isolated from the bacteria in these samples and the relative biological activities of the incoming versus the resident deoxyribonucleate were measured. This ratio shown in Table 2 is established at the earliest time of observation, 5 min. after the termination of exposure to deoxyribonucleate, and does not change with the growth of the transformed culture. In addition, the ratio assumes a value approximately equal to the absolute frequency of transformants observed in the first transformation.

Table 2. RELATIVE BIOLOGICAL ACTIVITY OF NEWLY INTRODUCED PROPERTY TO THAT OF A RESIDENT PROPERTY FOLLOWING GROWTH OF THE TRANSFORMED CULTURE

Ratio of number of cells transformed to total number of cells in transformed culture	Relative increase in turbidity of transformed culture at time of DNA re-isolation	Ratio of biological activities of newly introduced DNA to resident DNA
$6 \cdot 7 \times 10^{-3}$	(1·0)	$5 \cdot 2 \times 10^{-3}$
	1·5	$6 \cdot 7 \times 10^{-3}$
	2·2	$5 \cdot 4 \times 10^{-3}$
	3·1	$6 \cdot 1 \times 10^{-3}$
	3·5	$5 \cdot 4 \times 10^{-3}$
	4·5	$6 \cdot 0 \times 10^{-3}$
	6·1	$5 \cdot 5 \times 10^{-3}$
	25 0	$5 \cdot 5 \times 10^{-3}$

These observations give further evidence of the high efficiency with which fixed transforming deoxyribonucleate may give rise to transformed bacteria. It would appear that transforming deoxyribonucleate re-isolated a short time after fixation has suffered neither physical nor biological dilution, though it is admixed with deoxyribonucleate of the transformable host bacteria. Furthermore, it has been shown that during the growth which follows the fixation of the transforming deoxyribonucleate, this deoxyribonucleate increases at precisely the same rate as does the resident deoxyribonucleate of the transformed bacteria. This synchronization is already established at the earliest times that have been examined in these experiments.

II

By DR. MAURICE S. FOX

AN examination of re-isolated deoxyribonucleate from transformed populations of pneumococci, following moderately long exposures to transforming deoxyribonucleate, has indicated that the new deoxyribonucleate is fully synchronized with the resident deoxyribonucleate of the transformed bacteria from the earliest times that had been observed. In addition, it has been shown that passage of transforming deoxyribonucleate through transformable bacteria does not appreciably alter its biological activity (previous communication).

Further investigation of such re-isolated deoxyribonucleate immediately following short exposures to the transforming deoxyribonucleate has demontrated an intermediate state of the transforming deoxyribonucleate between its fixation by the bacteria and that state in which the production of transforming deoxyribonucleate is fully synchronized with that of the resident deoxyribonucleate of the transformed population. The deoxyribonucleate in this intermediate state is biologically inactive in transferring in a second transformation the property which it carries. In addition, in line with the segregation investigation being carried out in this laboratory by Hotchkiss, it has been possible to examine the appearance of genetic linkage occurring as the result of an interaction between entities present in the donor deoxyribonucleate and those present in the recipient bacteria, following fixation of such deoxyribonucleate.

The genetic properties that were studied are streptomycin resistance *S*, two readily distinguishable levels of sulphonamide resistance, *a* (fully resistant to 10 μgm. sulphonamide/ml.), and *d* (resistant to 40 μgm. sulphonamide/ml.), and the combined property, *ad* (resistant to 200 μgm. sulphonamide/ml.). Conditions for selection and quantitative measurement of transformed bacteria carrying these properties have been described[8]. The properties *a* and *d* have been shown to be closely linked[8]. Deoxyribonucleate isolated from bacteria carrying both properties yields on transformation, under the conditions used, about as many transformed cells with only the properties *a* or *d* as those carrying the combined property *ad*.

The general procedure followed is similar to that described in the previous communication. After a high-density suspension of transformable bacteria is exposed to deoxyribonucleate for a given time at 30° C., a high concentration of deoxyribonuclease (20 μgm./ml. Worthington, pancreatic) is added to stop any further fixation, and samples are chilled at 0° C. after various incubation times.

After thorough washing, deoxyribonucleate is re-isolated from the bacteria. More than 50 per cent of the newly introduced deoxyribonucleate phosphorus-32 is recovered. Its biological activity is determined by using this deoxyribonucleate to transform a new strain of pneumococcus with respect to one of the properties carried by the original donor deoxyribonucleate and one or more of the properties resident in the recipient bacteria used in the first transformation.

It has been shown in the previous communication that after moderately long exposure to deoxyribonucleate, the ratio of these two activities (newly introduced deoxyribonucleate)/(resident deoxyribonucleate), assumes a value equal to the frequency of transformants in the first transformation, and that this ratio remains constant during the further growth of the transformed population.

It is now found that after very short exposure times to deoxyribonucleate and immediate re-isolation, this ratio is only a very small fraction of the ultimate ratio observed after longer incubation. This ratio rises and becomes a larger and larger fraction of the ultimate ratio with increasing exposure times to deoxyribonucleate (Table 3). Thus, the fractional recovery of the newly introduced deoxyribonucleate increases with increasing exposure times in the first transformation.

Table 3. RECOVERY OF NEWLY INTRODUCED DNA AFTER VARIOUS EXPOSURE TIMES TO DEOXYRIBONUCLEATE (DNA) AT 30°

Time of exposure to DNA (min.)	Frequency of transformants	Ratio of input activity to resident activity for DNA isolated after 1 min. incubation at 37° C. with DNase	Fraction of input activity recovered	Ratio of input activity to resident activity after 2 hr. growth at 37° C.
3	2×10^{-4}	7×10^{-6}	5 per cent	$1 \cdot 5 \times 10^{-4}$
7	5×10^{-4}	10^{-4}	20 per cent	5×10^{-4}
15	$1 \cdot 2 \times 10^{-3}$	$3 \cdot 4 \times 10^{-4}$	31 per cent	$1 \cdot 1 \times 10^{-3}$

The time course of the recovery of the biological activity of the newly fixed deoxyribonucleate has been examined. After very short exposure (5 min.) to the transforming deoxyribonucleate, and re-isolation of deoxyribonucleate from samples of the transformed population that have been allowed increasing incubation times, measurement of the biological activity of such preparations of deoxyribonucleate shows increasing fractional recoveries of the newly introduced deoxyribonucleate. The ratio of the biological activity of the newly introduced deoxyribonucleate to that of the resident material rises to a constant value determined by the frequency of transformants obtained as a consequence of the original 5-min. exposure to the deoxyribonucleate (Fig. 2). This level is identical with that observed after long exposures to deoxyribonucleate (previous communication).

The rates of recovery of the lost biological activity are the same when the newly introduced deoxyribonucleate comes from an organism carrying the properties *S*, *d* or *ad*. In addition, the rates show a dependence on temperature such that at 30° the half-time for recovery is about twice as long as at 37°.

Making use of the possibility of building up the linkage group *ad*[8] from its component parts, a transformable strain of pneumococcus carrying the properties *S* and *a* has been transformed with deoxyribonucleate isolated from a strain carrying the property *d*. The biological activity of the re-isolated deoxyribonucleate is then tested on bacteria carrying none of these properties. The recovery of deoxyribonucleate carrying the newly introduced *d* property follows the time course already described. It is also possible to observe the appearance of a new biological entity that is capable of introducing simultaneously both properties *a* and *d*. The appearance of this new entity, a product of the interaction between the newly introduced and the resident deoxyribonucleates, follows a time course roughly similar, with a half-time about twice as long as that observed for the recovery

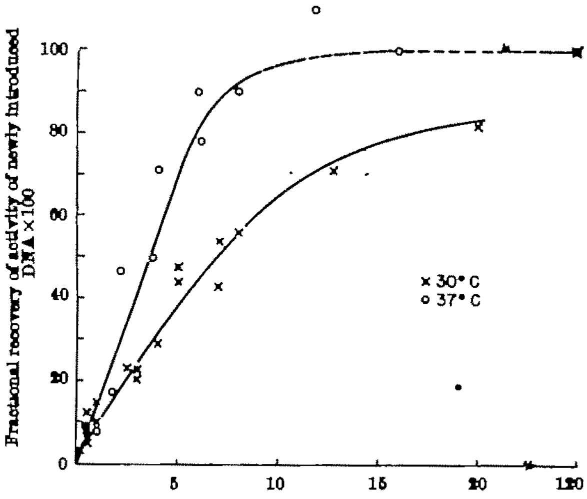

Fig. 2. Fractional recovery in re-isolated deoxyribonucleate of biological activity of newly introduced deoxyribonucleate as a function of time following termination of a 5-min. exposure to transforming deoxyribonucleate with deoxyribonuclease

of the *d* marker that has been introduced (Fig. 3). Thus, the biological activity of the newly introduced deoxyribonucleate recovers with a half-time of about 3–4 min. and the linking of this new deoxyribonucleate with that present in the genome of the recipient cell occurs with a half-time of about 6 min. at 37° C.

The fractional recoveries shown in Figs. 2 and 3 are measured as the ratio of the biological activity of the newly introduced deoxyribonucleate to that of the resident deoxyribonucleate. They are expressed relative to the ultimate ratio observed for deoxyribonucleate isolated after 2-hr. incubation at 37° C. of a dilution of the transformed culture. This incubation is sufficient to allow about a ten-fold increase in the number of bacteria. The ultimate ratio agrees within experimental error with the absolute frequency of bacteria transformed for a single property. For the cases in which the linkage group *ad* is observed, the ultimate ratio assumes a value equal to one-half the frequency of *ad* transformants in the first transformation. This factor of two difference between the frequency of transformants and the recoverability of the linkage group is to be expected since deoxyribonucleate carrying the *ad* property regularly gives equal numbers of *d* and *ad* transformants.

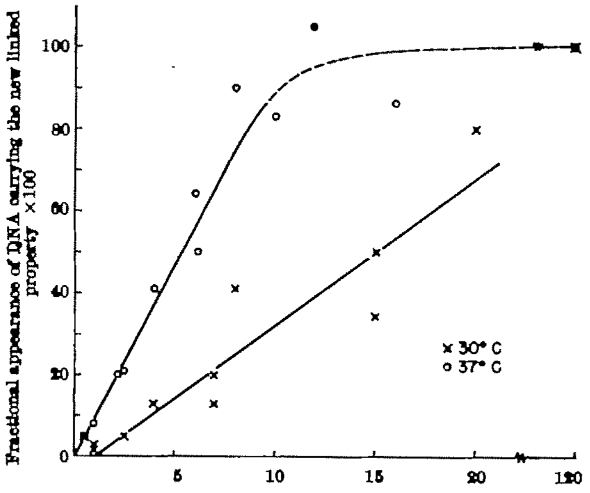

Fig. 3. Fractional appearance, in re-isolated deoxyribonucleate, of biological activity manifesting linkage between the newly introduced and resident deoxyribonucleate. A 5-min. exposure to transforming deoxyribonucleate is terminated with deoxyribonuclease and deoxyribonucleate is re-isolated from bacteria allowed the indicated additional incubation time

Thus, there exist at least two processes that transforming deoxyribonucleate may undergo following its fixation by bacteria. One has as its consequence the recovery of the biological activity in re-isolated deoxyribonucleate and the second results in the specific coupling of this newly introduced deoxyribonucleate with that resident in the recipient bacteria. The difference between those two processes may be further examined by a consideration of the relative transforming activities of a given deoxyribonucleate re-isolate with regard to the newly introduced property and the linked property.

Since deoxyribonucleate from bacteria carrying the linkage group *ad* yields on transformation about twice as many transformants bearing *d* (including *ad*) as *ad*, deoxyribonucleate isolated from a transformed population in which about a half of the transformed cells are *d* only and half are *ad* would be expected to yield four times as many *d* (including *ad*) as *ad* transformants. When deoxyribonucleate is re-isolated from a transformed population in which deoxyribonucleate from bacteria carrying the linkage group *ad* is introduced into sulphonamide-sensitive bacteria, the ratio:

$$\frac{\text{yield of } d\text{, including } ad\text{,}}{\text{yield of } ad}$$

(*d*/*ad*) assumes a value of close to four from very early times (Table 4).

Table 4. RELATIVE ACTIVITY OF A SINGLE PROPERTY, NEWLY INTRODUCED, COMPARED WITH A LINKED PAIR OF PROPERTIES (*a*) BOTH MEMBERS OF THE LINKAGE GROUP, (*b*) ONE MEMBER OF THE LINKAGE GROUP, NEWLY INTRODUCED, AND ONE MEMBER RESIDENT IN THE RECIPIENT BACTERIA

(*a*) DNA from strain *ad* into sulphonamide-sensitive strain

Time at 30° before re-isolation of DNA (min.)	½	3	7	14	20	120 (at 37° C.)
d / *ad*	3·6	3·4	4·8	4·0	3·9	4·2
Per cent *d* recoverable	4	21	54	70	100	100

(*b*) DNA from strain *d* introduced into strain *Sa*

Time at 30° before re-isolation of DNA (min.)	½	2½	7	20	20 (at 37° C.)
d / *ad*	13	10	9	6	4
Per cent *d* recoverable	6	14	40	100	100

In the experiment described in Table 4, in which deoxyribonucleate from bacteria carrying the property *d* is introduced into bacteria carrying the property *a*, the ratio *d* : *ad* assumes a high value at early times and approaches an equilibrium value of four at longer incubation times. The fact that the ratio *d* : *ad* is independent of the frequency of bacteria transformed either to *d* or *a* excludes the possibility that any appreciable fraction of the *ad* transformants observed are the consequence of a random double event.

The difference in the behaviour of the *d* : *ad* ratio as a function of time between the two experiments described shows that the recovery of *ad* activity from newly introduced deoxyribonucleate carrying *ad* is a different process from that in which *ad* activity appears as a consequence of an interaction between the newly introduced deoxyribonucleate and that of the recipient bacteria. It is impossible as yet to distinguish with certainty between a sequential process, recovery of *d*, followed by linking *a* and *d*, and two independent simultaneous processes occurring at different rates.

It is also not as yet possible to say whether or not synthesis of deoxyribonucleate is an obligatory requirement for either the recovery or the integration of the new deoxyribonucleate. Both processes are complete within a period during which there has been little overall growth; the increase in turbidity of the total culture may be less than 10 per cent. Earlier observations have demonstrated that transforming deoxyribonucleate re-isolated after prolonged exposures to deoxyribonucleate, followed by incubation for 5 min. at 37° with deoxyribonuclease, has suffered neither physical nor biological dilution. These times are long enough for both these processes to have approached completion. Furthermore, concentrations of 5-fluorodeoxyuridine thirty times higher than that necessary completely to inhibit bacterial growth fail to inhibit either reaction. Preliminary measurements of incorporation of phosphorus-32 into deoxyribonucleate during this period suggest that the net new synthesis of deoxyribonucleate by such transformed bacteria is less than 5 per cent.

Thus, it may be concluded that transforming deoxyribonucleate becomes integrated into the genome of the recipient bacteria during the first few minutes following the fixation of the deoxyribonucleate. Transforming deoxyribonucleate re-isolated immediately after its fixation has suffered a loss of function, and this function is rapidly recovered on incubation of the transformed bacteria. In addition to a recovery of function, the newly fixed deoxyribonucleate may become genetically linked to deoxyribonucleate resident in transformed bacteria during this period. Preliminary observations suggest that little or perhaps no new deoxyribonucleate synthesis is required for either the recovery of function or the appearance of genetic linkage.

The technical assistance of Miss I. Miller is gratefully acknowledged.

EFFECT OF ACRIDINE ORANGE ON LIVING BULL SPERMATOZOA

By C. VAN DUIJN, JUN.

Biophysics Department, 'Schoonoord' Research Institute for Animal Husbandry, Hoogt 10, Utrecht

SINCE the introduction of the acridine orange vital fluorochroming technique in 1940[1-3] vital fluorochroming of spermatozoa with this substance was performed for the first time by Strugger and Rosenberger in 1944[4]. Goat spermatozoa showed different resistance to varying concentrations of acridine orange. Using a dilution of 1:80,000 in a glucose-phosphate buffer after Milovanov, 100 per cent motility could be maintained for two days in complete darkness at 8° C. In artificial insemination experiments with fluorochromed semen, fertilization was accomplished in 21 goats out of 27 and this was followed by normal development and birth of young.

Although most living cells do not suffer toxic effects from acridine orange if this is used in very low concentration[3,5,6,7] some cells may be more susceptible. Personally, I found that mouse lymphoblasts are killed by acridine orange in a concentration of 1:5000; even in concentrations as low as 1:50,000 reproduction was impaired[8]. With human spermatozoa, susceptibility was found to be rather high, 1:10,000 being about the highest concentration that may be used without killing them instantaneously, and even then great care has to be taken as to the method of application[9]. Susceptibility also seemed to depend on the activity of the specimens; the more active the spermatozoa, the quicker they were killed.

In recent years Vandemark *et al.*[10,11] have applied acridine orange for evaluating the motility of bull spermatozoa. They did not observe toxic reactions with concentrations of 1:40,000 up to 1:10,000 during 15 min. incubation at 37° C. and they observed only a slight reduction in motility after storage at 5° C. for 24 hr. These estimations, however, were based on visual observations only and not on exact measurements.

Contrary to these observations, I have found a definite adverse effect of acridine orange on living bull spermatozoa, both with respect to the number of normally moving sperms and their mean velocity, measured with high accuracy with the photoelectric method developed by Rikmenspoel[12,13].

Freshly ejaculated semen was allowed to cool to 25° C. and then diluted 10 times with an ultramicroscopically clear egg-yolk—citrate buffer[14] (pH 6·75 ± 0·05 at 22–23° C., corresponding to pH 6·80 ± 0·05 at 37° C.) of 30° C. After this first dilution the samples were slowly cooled to ~ 4° C. by placing the tubes in a larger glass beaker which in its turn was placed in a Dewar vessel with ice. Further four-fold dilutions were made with portions of the same buffer to which varying amounts of acridine orange had been added to get a range of concentrations of 1:200,000–1:5000. The fluorochrome-containing buffer was poured gently on top of the fluid to avoid mixing, and the sample was allowed to stand in the Dewar vessel for 20 min. before mixing was accomplished by gentle turning; this cautious procedure is required to avoid shocking the specimens when semen is diluted. After mixing, drops (13·5 ± 0·3 μl.) of the diluted semen were brought into a micro-chamber by means of a leukocyte pipette and warmed up for 5 min. to 37° C. Then the dark-field image of individual swimming spermatozoa was projected on to a small aperture 'viewed' by a photomultiplier through an auxiliary lens. Every time a sperm passes by the area 'seen' by the photomultiplier the latter receives light impulses and emits a corresponding number of photo-electrons. The resulting fluctuating photocurrent is amplified and recorded. From the recordings the velocities of individual spermatozoa can be measured, discrimination between normal and abnormal movements is possible and the method also allows one to determine the total number of normally moving sperms.

The mean velocity of the spermatozoa with normal movement was found to decrease proportionally with the square root of the fluorochrome concentration, according to the equation:

$$\bar{v}_c = \bar{v}_0 - 3900\sqrt{c} \quad \mu/\text{sec.}$$

where $\bar{v}_c$ is mean velocity at fluorochrome concentration c; $\bar{v}_0$ is mean velocity without fluorochrome addition; and c is concentration of acridine orange expressed in weight ratios, for example, $c = 2 \times 10^{-4}$ is equivalent to the expression 1:5,000.

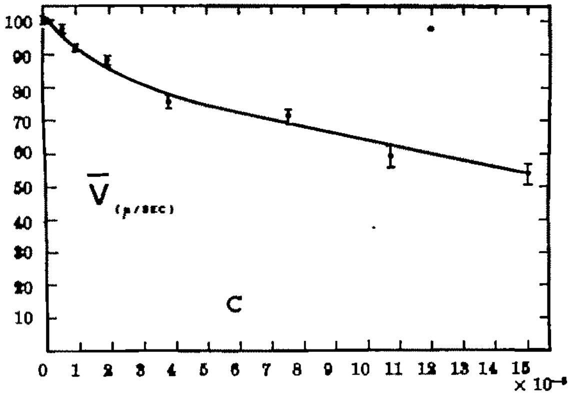

Fig. 1. Mean velocity of normal bull spermatozoa as a function of the concentration of acridine orange. The plotted results have been obtained by pooling all v values of the individual spermatozoa from five ejaculates from four different bulls at each concentration

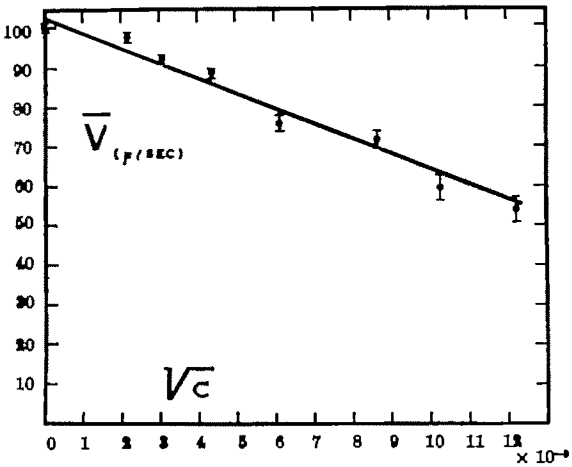

Fig. 2. Mean velocity of normal bull spermatozoa as a function of the square root of the concentration of acridine orange. Same results as depicted in Fig. 1

This relationship is shown by Figs. 1 and 2 representing the data obtained in a series of measurements of 5 ejaculates from 4 different bulls of Dutch-Friesian and red-and-white Meuse-Rhine-Yssel breed. It is shown that the mean velocity at an acridine orange concentration of 1:10,000 has decreased to 62 per cent of that measured in the control without fluorochrome addition under the conditions of the experiment, which include 7 min. irradiation with white light obtained from a 6 V., 5 amp. incandescent microscope bulb, operated at 6 amp. The mean irradiation period is only half this, since the period covers the total time required for recording.

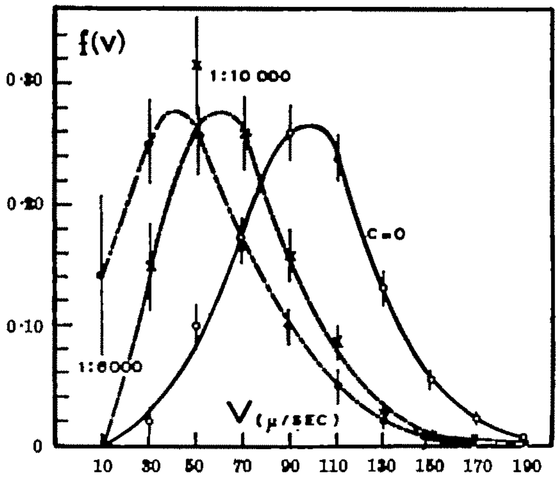

Fig. 3. Normalized velocity frequency distributions of normal bull spermatozoa with acridine orange 1:6,000 and 1:10,000 compared with control ($c = 0$) without fluorochrome

The velocity frequency distributions not only shift to lower values, but their shape is altered, too, as shown in Fig. 3. Whereas at low concentrations the curves do not differ much from that obtained for the control, the distributions become definitely skew at concentrations of 1:10,000 and higher.

The number of normally moving specimens also decreases with increasing fluorochrome addition (Figs. 4 and 5). The effect is not bull-specific, the slopes of the regression lines being identical within the experimental errors for all experiments. Although there

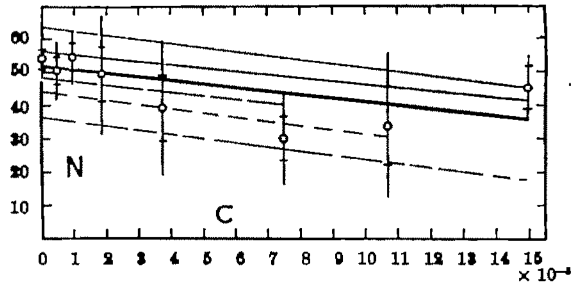

Fig. 4. Number of normally moving bull spermatozoa (arbitrary units) as a function of the concentration of acridine orange. Dotted lines: regression lines of the individual experiments; full line: regression line of all data, with indications of the standard deviations and the standard errors of the means of the individual figures

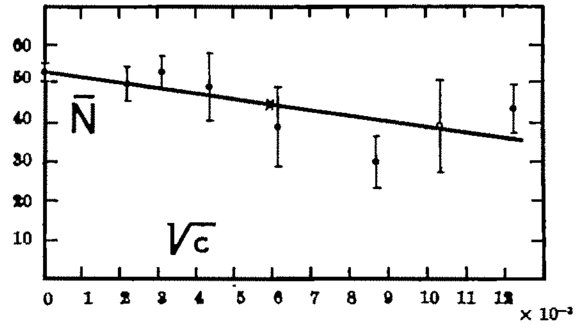

Fig. 5. Number of normally moving bull spermatozoa (arbitrary units) as a function of the square root of the acridine orange concentration. The mean values $\bar{N}$ obtained by averaging the data obtained for the individual ejaculates have been plotted with the standard errors of the means. Comparison with Fig. 4 shows that there is no significant difference in fitting the data to proportionality with either c or $\sqrt{c}$

might be reason to assume that this relationship would also be proportional to the square root of the concentration, the curves show that in this case the data can equally well be fitted by an equation of the type $N_c = N_0 - k.c$ as by one where $N_c = N_0 - k\sqrt{c}$ (N_c and N_0 being the numbers of normally moving sperms, expressed in arbitrary units, at concentration c and 0, respectively). At an acridine orange concentration 1:10,000 the number of spermatozoa showing normal movements is shown to have fallen to approximately 80 per cent of that of the control without fluorochrome addition.

Acridine orange exerts a powerful photodynamic action[5] like all fluorescent dyes[15–17], and in preliminary experiments I have found a great difference in the rates of decrease of velocity with time in illuminated samples of semen to which acridine orange had been added and the controls, consisting of a similar fluorochromed sample kept in the dark and samples without fluorochrome addition kept in darkness and under illumination. Even native bull spermatozoa are highly susceptible to light; Norman and Goldberg[18] found a progressive decline in metabolic activity, followed by the premature death of the cells, showing all characteristics of a photodynamic action, due to the effect of a photosensitizer which is an intrinsic component of the cell. That the adsorption of acridine orange can add to its effect will not be surprising.

Since the technique employed by Vandemark *et al.*[11] implies the use of pure ultra-violet irradiation it seems unlikely that the discrepancy between their results and mine would be due to differences in photosensitizing effects, although this might require additional information on the dependence on wave-length of this effect of acridine orange with respect to spermatozoa. At present it seems more likely that the discrepancy can be accounted for by the low reliability of visual motility estimations in general as compared with exact measurements of velocity.

In recent years it has repeatedly been asserted that acridine orange should be adsorbed preferentially to nucleic acids[6,7,19–25]. Whereas it may be that this applies to certain types of material and special conditions of application[4,20,26] it would lead to serious mistakes if one should take excessive adsorption of acridine orange in itself as a test for nucleic acids. The original investigations by Strugger[5] point to the great diversity of substances that may heavily adsorb this fluorochrome, whereas I demonstrated that in human spermatozoa strong red fluorescence can be obtained after total removal of nucleic acids by extraction with hot trichloroacetic acid[9,27]. Neither in bull nor in human spermatozoa has differentiation between nucleic acid-containing parts (nucleus, mitochondria in the midpiece, and the axial filament of the tail[27]) and the cytoplasmic components been observed in the living state. In bull spermatozoa the entire head appears fluorochromed rather homogeneously, both in the living and the dead state, allowing the fluorochrome method to be used as most reliable for determining biometrical data of the external head shape and its area[28].

Although it would not seem unreasonable to assume that at least part of the adverse effect of acridine orange might be due to adsorption to nucleic acids, this would require experimental corroboration. The mathematical expression of the effect with respect to the swimming velocity is in agreement with a simple adsorptive process following the Freundlich adsorption isotherm, but this is insufficient for further deductions.

A further account of the investigations, which are being continued, will be published elsewhere.

EFFECT OF GLYCERINE ON THE X-RAY SENSITIVITY OF *SERRATIA MARCESCENS*

By DR. D. L. DEWEY

British Empire Cancer Campaign Research Unit in Radiobiology,
Mount Vernon Hospital, Northwood, Middlesex

IN 1951 Burnett *et al.*[1] reported that many alcohols and glycols, at concentrations in the 0·1–1 *M* range, protected *Escherichia coli B/r* against the lethal effects of irradiation at 2° C. Later Marcovich[2], using *Escherichia coli K*12 (λ), observed similar protection against aerobic irradiation by glycerine and four other similar compounds. Maximally protected organisms had about the sensitivity of anaerobic organisms, and no protection was observed against phage induction which he had reported previously to

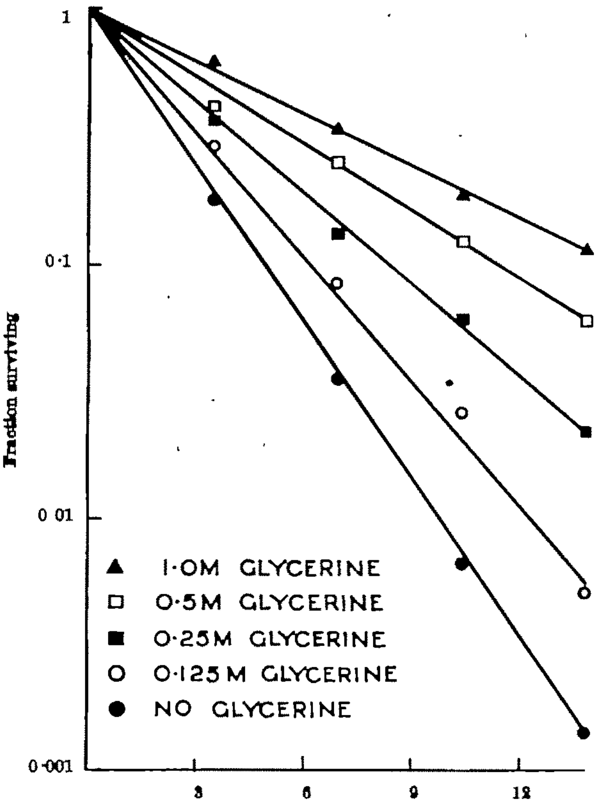

Fig. 1. Logarithmic survival of *Serratia marcescens* suspended in various glycerine concentrations and equilibrated with oxygen during X-irradiation

be independent of the presence of oxygen at the time of irradiation. This phenomenon of radiation protection by glycerine has been re-examined using the small red pigmented bacterium, *Serratia marcescens*, and the observations indicate that protection of aerobic organisms is brought about by some mechanism other than oxygen scavenging or competition with oxygen for radiation-induced radicals, and that organisms which are anaerobic when irradiated can also be substantially protected by the presence of glycerine.

Overnight cultures grown at 25° in unaerated nutrient broth were diluted in 0·015 *M* phosphate buffer at *p*H 7 shortly before irradiation by 200-kV. X-rays (1·6 mm. aluminium filter) at 1,000 r./min. in a 'Perspex' vessel which provided for continuous bubbling and thermostatic control. In the present experiments, the bacteria were diluted and suspended in the glycerine solution a few minutes before irradiation. A control sample was taken just before irradiation, and an experimental sample was taken immediately after irradiation. Both samples were then appropriately diluted in 0·015 *M* buffer containing no glycerine, and plated out in nutrient agar. Visible colony counts were made after 48 hr. incubation at 25°. The fraction of cells surviving to form a visible colony was used as a measure of the X-ray damage.

For anaerobic experiments, nitrogen was bubbled through the bacterial suspension for 20 min. before taking a control sample. Gassing was then continued for a further 5 min. before irradiation in case any atmospheric oxygen had entered the apparatus during sampling. The exit gas was passed through a Hersch cell[3] and any trace of oxygen impurity continuously monitored. Any anaerobic experiments in which the oxygen concentration rose above 20 parts per million have been excluded.

The effect of glycerine on survival of bacteria gassed with 100 per cent oxygen during irradiation is shown in Fig. 1. When plotted as the logarithm of the surviving fraction against linear dose, the points lie on straight lines through the origin at all glycerine concentrations. The slope of the regression line through each set of points has been determined by mean square analysis. The effect of glycerine on the radiosensitivity of bacteria appears to follow the second-order kinetics type of equation used by Michaelis and Menten[4] for enzymes, and Alper and Howard-Flanders[5] for the effect of oxygen on the radiosensitivity of bacteria. If this is so, the effect of glycerine on the sensitivity of bacteria to X-rays can be expressed in the form:

$$\frac{D}{D_0} = \frac{mG + K}{G + K}$$

where D is the 37 per cent dose for the bacteria suspended in a glycerine solution of concentration G, D_0 is the 37 per cent dose in the absence of glycerine. m and k are constants. By plotting D_0/D against $D_0 - D/D \times G$, a straight line should be obtained. By extrapolating this line to cut the axis, values of m and k can be determined. The best line determined by the points from Fig. 1 plotted in this way gives a value for m of 5·25, this being the ratio of the sensitivity of the bacteria in the absence of glycerine to their sensitivity in infinite glycerine concentration. The concentration of glycerine required to give half the theoretical maximum is equal to $K = 0·9$ molar. In Fig. 2 the 37 per cent dose has been plotted against glycerine concentration. The solid line is the theoretical curve using the above values of m and k. If glycerine is competing with oxygen for active sites, or preventing oxygen from reaching these active sites then the concentrations of glycerine required to produce a given amount of protection should depend on the concentration of oxygen. The experiment was repeated using a mixture of 1 per cent oxygen in nitrogen in the gas phase. The results shown in Fig. 2 demonstrate that the protective effect of glycerine is independent of a change

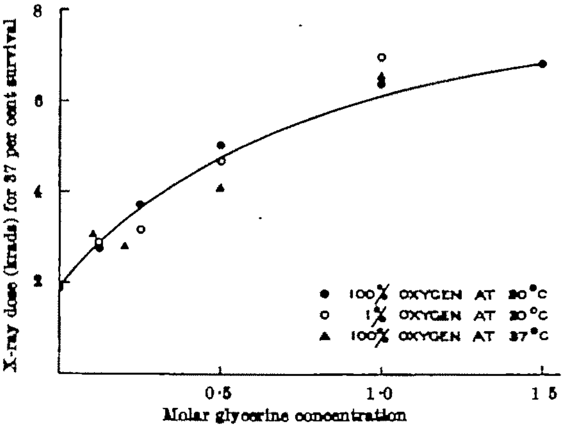

Fig. 2. The effect of glycerine on the aerobic X-ray sensitivity of *Serratia marcescens*

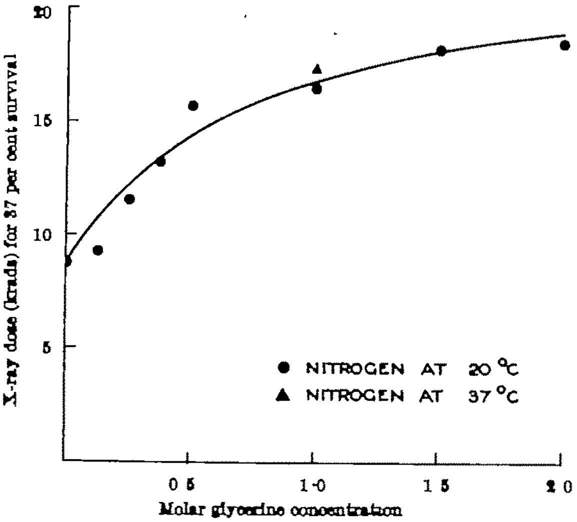

Fig. 3. The effect of glycerine on the anaerobic X-ray sensitivity of *Serratia marcescens*

in oxygen concentration by a factor of 100. Another experiment, using 100 per cent oxygen but at 37°, demonstrates that protection by glycerine has little or no temperature effect. Control bacteria which were suspended in 1·5 *M* glycerine within a minute after they were irradiated, and then kept in glycerine for the same length of time as the experimental bacteria, were not protected against the full X-ray damage.

Glycerine also protected cells from the effect of X-rays when the bacterial suspension was gassed with nitrogen or with 10 per cent nitric oxide in nitrogen anoxia. The kinetics of the effect in the presence of nitric oxide has not yet been worked out. The effect of various glycerine concentrations combined with pure nitrogen is shown in Fig. 3. Using the same procedure as above, the value of m was 2·66 and k was 0·8 molar.

Wood[6] has protected yeast cells against X-ray damage by high concentrations of glycerine. He has interpreted the results as a dehydration of the cells. The overall effects of glycerine on *Serratia marcescens* is very similar to the radioprotection of cysteine on *E. coli* reported by Kohn and Gunter[7]. The effective concentrations of the two chemicals are also very similar. Kohn and Gunter mention the trapping of free radicals or the formation of mixed disulphides as possible protective mechanisms. Burns[8] has been able partially to protect diploid but not haploid yeast against anoxic radiation damage with p-chloromercuribenzoate and suggested a masking of sulphydryl groups. No final answer to the mechanism of glycerine protection can yet be given. But, assuming that it protects against the indirect effects of radiation, and extrapolating to infinite glycerine concentration, the dose reduction factor of 2·66 would mean that only 37 per cent of the damage in the anaerobic system was due to direct effects.

I wish to thank Dr. L. H. Gray and Dr. J. W. Boag for helpful discussions, and Mr. J. Steadman and Miss J. Liddon for technical assistance.

BIOSYNTHESIS OF CELLULOSE BY *ACETOBACTER ACETIGENUM*

By Dr. A. M. BROWN and Dr. J. A. GASCOIGNE

British Rayon Research Association, Heald Green Laboratories, Wythenshawe, Manchester, 22

Morphology of *Acetobacter acetigenum* and Cellulose Synthesis

In the course of a systematic study of cellulose biosynthesis by the bacterium *Acetobacter acetigenum* our attention has turned to the possible function of the cell wall and capsule (that is, a distinct envelope of polysaccharide material) in the production of cellulose. Methods of preparing cell-free extracts of *Acetobacter xylinum* capable of promoting cellulose synthesis have been reported recently. In the Colvin method[1] the extract is prepared from unbroken cells; in other methods[2-4] the extract is prepared from cells which have been disrupted by mechanical or ultrasonic disintegration. An important difference in the behaviour of broken and unbroken cell extracts lies in the ability of the former to incorporate into cellulose the glucose molecule from uridine diphosphate glucose. This observation suggested that it would be advantageous to examine systematically the function of the various cell components in cellulose synthesis. In this article we report that, although *A. acetigenum* is not capsulated, its cell wall plays an important part in cellulose biosynthesis.

Cells of *A. acetigenum* (N.C.I.B. 8132) were grown on standard malt wort[5], and were then inoculated into a sterile medium (*G.M.S.*) of the composition: D-glucose monohydrate, 1 per cent; yeast extract (Oxoid), 0·2 per cent; potassium dihydrogen phosphate, 0·3 per cent; ammonium sulphate, 0·3 per cent; crystalline magnesium sulphate, 0·2 per cent, all by weight in water adjusted to pH 6·0. After growth for 40 hr. at 28°, the cells were harvested by the method of Hestrin and Schramm[6]. Microscopic examination of the cells at this stage revealed adherent, ill-defined material surrounding some cells. The cells were then washed three times by suspension in water and centrifugation, and were finally passed through a sintered glass filter (porosity 3). After centrifugation, the precipitated cells were examined by ordinary and phase contrast microscopy in preparations stained by the wet indian ink method[7], dry-film indian ink method[8], and a mordanting procedure[9]; capsules could not be observed surrounding any of the cells. Washed, filtered cells, when reinoculated into standard malt wort, rapidly produced cellulose. Repetition of these experiments with *A. acetigenum* cells after growth for 72 hr., 7 and 14 days failed to reveal any capsulation. As a control experiment, well-capsulated cells of *Klebsiella pneumoniae* were submitted to the same washing and filtration procedures, and distinct capsules were observed under the microscope.

The partial removal of cell walls has been accomplished by the growth of Gram-negative bacteria in the presence of antibiotics[10], or by the partial hydrolysis of cells in the presence of lysozyme and a chelating agent[11]. *A. acetigenum* cells were grown at 28° in the *G.M.S.* medium, to which was added benzyl penicillin (sodium salt) at concentrations of 100, 500 and 1,000 units per ml. For 48 hr. little growth occurred in any of the cultures, and microscopic examination showed many spherical large bodies in addition to normal rod-shaped cells. After this time, slow cellulose formation occurred at the two lower penicillin concentrations, but in no case was synthesis so rapid as in the absence of penicillin. The swelling of cells could not be halted by the addition of polyethylene glycol or sucrose as stabilizers, so that protoplasts could not be isolated.

It was found that cells harvested from 48-hr. *G.M.S.* cultures (without penicillin), and allowed to rest in sterile water at 2° for 2 hr., could be lysed in the following mixture[12]: crystalline egg lysozyme 13·3 μgm./ml.; ethylenediamine tetraacetic acid (sodium salt), 1·4 μmoles/ml.; sucrose, 0·06 m.moles/ml.; 2-amino-2-hydroxymethylpropane-1:3-diol buffer (*p*H 8·5), 33·3 μmoles/ml.; and wet compacted cells, 0·2 ml./ml. After 30 min. at 28°, many protoplasts could be seen under the microscope; more prolonged lysis disrupted the protoplasts giving rise to almost transparent 'ghost' membranes. At all times a few normal, rod-shaped cells remained in the solutions, but differential centrifugation enabled a partial separation to be made. The protoplast-rich fraction, containing very few normal cells, on inoculation into either *G.M.S.* medium or a sucrose solution (*M*) containing mineral salts and yeast extract, did not produce any cellulose for more than 48 hr. at 28°; with normal cells cellulose becomes visible after growth for 3 hr. at 28°. The resumed synthesis with protoplast-containing media may have been due to the recovery of the few normal cells in the inoculum from metabolic upset. However, this partial removal of the cell wall certainly interfered with cellulose synthesis.

We have observed that the growth of *A. acetigenum* in *G.M.S.* medium in both shaken and aerated cultures at 28° produced very little cellulose, and examination showed the presence of large cells in such cultures, similar to the large bodies produced by lysozyme action in the absence of stabilizers. These results have interesting bearings on the findings of Walker and his co-workers[13,14], who observed changes in colonial morphology, and described the cells as 'cellulose-less mutants'. Some doubt has been cast on the purity of such cultures, and it has been suggested that Walker's observations could have arisen from culture contaminants[15]. The formation of protoplasts or even large bodies retards and possibly completely halts cellulose synthesis by such cells, and thus such altered cells could be regarded as cellulose-less mutants. From these observations, it is suggested that the bacterial cell wall plays some part in cellulose biosynthesis.

Extracellular Synthesis of Cellulose by *Acetobacter acetigenum*

THE formation of cellulose by *Acetobacter xylinum* from ultrafiltered ethanol extracts of glucose metabolizing cells has been recorded by Colvin[1]. Similar findings are now reported with *Acetobacter acetigenum*, together with some modifications of the Colvin procedure.

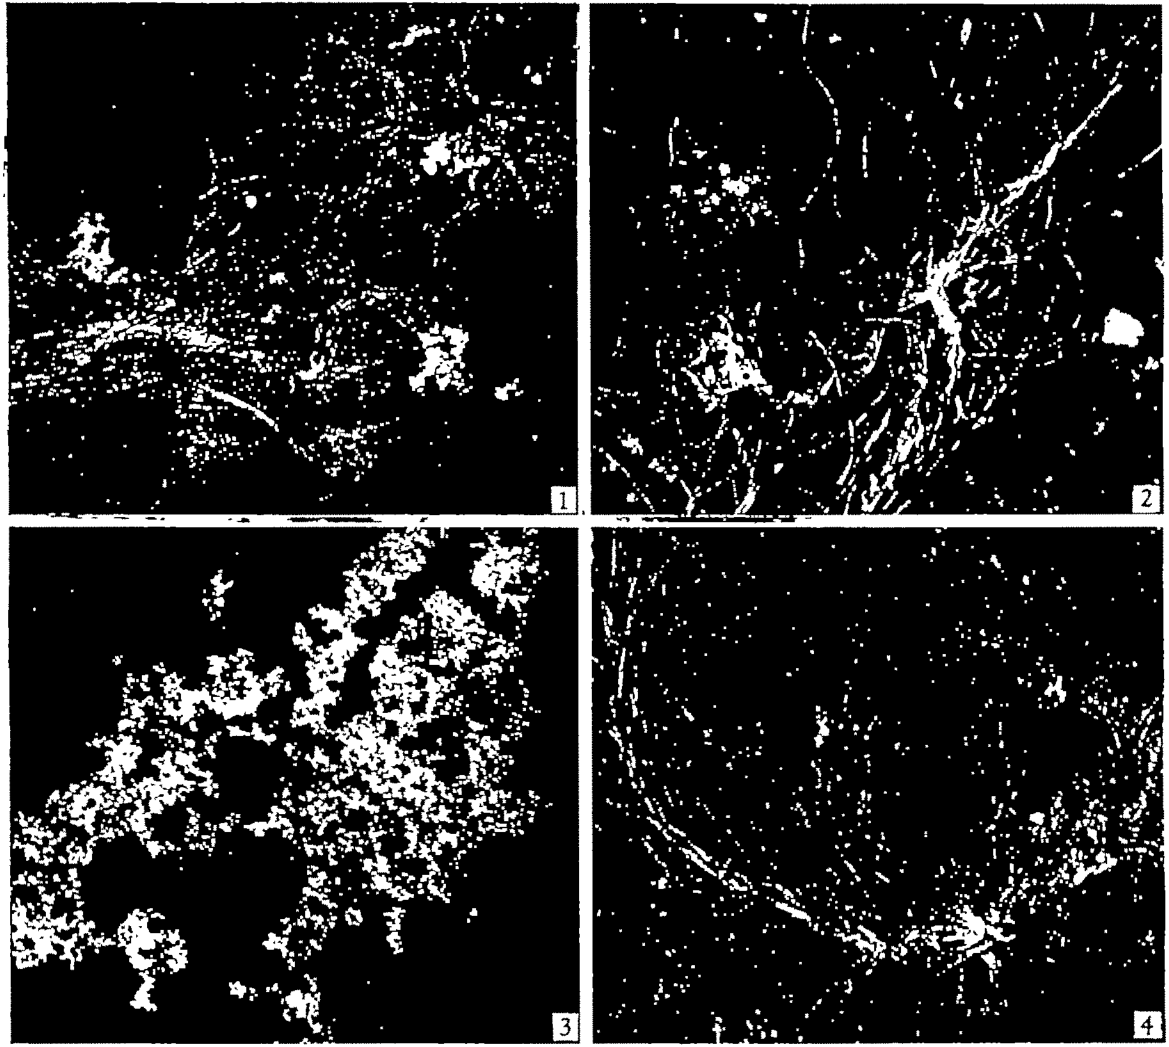
Acetobacter acetigenum (N.C.I.B. 8132) was inoculated from standard malt wort cultures[8] into a medium (*G.M.S.*, see previous communication). The cultures (200 ml. each in 1-l. conical flasks) were incubated at 28° for 40 hr., the cellulose produced then being in the form of an almost transparent gel. Cells were obtained from this gel by the method of Hestrin and Schramm[6]. The cells were washed, incubated with glucose solution, and the precursor of cellulose and the enzyme system were extracted from the cell suspension with ethanol. After removal of cells, the extract was evaporated to give an aqueous solution in which the enzymic reaction with the precursor took place. After evaporation to dryness, the residue was washed with alkali to remove protein and non-cellulosic materials, and then submitted to electron microscopy; all the above operations were carried out exactly as described by Colvin[1].

The resulting electron micrograph (Fig. 1) shows clearly the alkali-resistant, enzymically synthesized microfibrils, although they appear to differ from microfibrils obtained by ultrasonic disintegration of bacterial cellulose (obtained from *A. acetigenum* cultures) and shown in Fig. 2. Acid hydrolysis (2 *N* sulphuric acid for 18 hr. in a sealed tube at 100°) of the alkali-resistant fibrillar residue produced glucose only, when analysed by paper chromatography. Another sample of the ethanol extract was heated in steam at 125° for 20 min. to denature the enzymes present, and then treated as described by Colvin, with the result shown in Fig. 3, revealing no synthesis of cellulose.

Similar alkali-insoluble fibrillar material was obtained by a similar sequence of operations, starting by dropping the gel cellulose into ethanol (to give 75 per cent ethanol concentration, by volume), and then following the Colvin procedure with the ethanol extract.

The efficiency of sinter-glass filters of porosity 5 on 3 for the removal of *A. acetigenum* cells and of microfibrils was tested, in order to examine an alternative method to ethanol extraction. Filtration of an aqueous suspension of cells through such a filter gave a clear filtrate, which contained no cells on examination in the light microscope. Portions of this filtrate were inoculated into standard malt wort[10], and were incubated at 28° for 7 days; no cellulose was formed and no cells could be detected. Thus the filter removed cells completely. Bacterial cellulose was disintegrated ultrasonically (9 kc./s. for 1 hr. at 2°) in water to give microfibrils visible under the electron microscope. Filtration of this suspension through the glass filter, followed by centrifugation of the filtrate at $30 \times 10^3 g$, gave no visible residue, and no microfibrils could be observed in either the supernatant liquid or in washings from the centrifuge tube under the electron microscope. Thus the glass filter could be used to remove microfibrils from solution.

A *G.M.S.* culture (200 ml.), grown for 40 hr. at 28°, was passed through the glass filter and the filtrate was incubated for 1 hr. at 28°. The filtrate was then centrifuged at $30 \times 10^3 g$, and the pre-



Figs. 1–4. Electron micrographs of cellulose microfibrils (× c. 13,500) and of denatured enzyme experiment

cipitate was submitted to electron microscopy, with the result shown in Fig. 4; again clear evidence for the formation of microfibrils was obtained. These microfibrils were insoluble in sodium hydroxide solution (2 N at 100° for 5 min.), and again their appearance differed from both the samples obtained above (Figs. 1 and 2). The reasons for these differences are not yet known. The addition of sterile aqueous solutions of α-D-glucose-1-phosphate, uridine diphosphate glucose (sodium salt), cellotetraose and cellohexaose (2 mgm. each in 2 ml. water) separately to the ultrafiltered culture medium gave no visible quantity of cellulose, as would have been expected from enzymic synthesis if these substances were extracellular precursors of cellulose.

These experiments confirm the findings of Colvin[1] that the final stage (or stages) of cellulose biosynthesis by *Acetobacter* spp. occurs extracellularly, and also lend weight to the findings of Schramm, Gromet and Hestrin[16] that glucose-1-phosphates and uridine diphosphate glucose provided exogenously are not converted to cellulose on the outer surface of *A. xylinum* cells. All these findings support the hypothesis that an exogenous substrate (probably glucose) enters the cell, and is converted to a precursor which can be transported out of the intact cell and converted to cellulose extracellularly.

We wish to acknowledge the help and advice of Drs. J. Dlugosz and A. Sharples, and the practical assistance of Miss D. L. Peat and Mr. C. D. Shorey. This work forms part of the fundamental research programme of the British Rayon Research Association.

PHYSICS

Electromagnetic Standing Waves and Ball Lightning

BY now it is well known[1–3] that charged particles moving in harmonically oscillating vacuum electromagnetic fields can be subject to time-average forces which establish a virtual potential minimum for them. The matter takes on a different aspect when the number of particles is so large as to form a highly conducting plasma, as in Kapitza's theory of ball lightning[4]. Then, quite aside from the details of the particle motions, we know that the radiation pressure of the inflowing electromagnetic radiation is exerted on the energy-dissipating plasma. Thus, if the maintenance of a local ball of fire requires about 20 kW. (2×10^{11} dyne cm. sec.$^{-1}$), the total force, irrespective of direction, associated with this energy conversion will be 6·7 dynes. To the extent that, besides the 20 kW. absorbed, there may be energy reflected, this number will be greater. A reflected 20 kW. will contribute 13·3 dynes. This is far too little to hold a fire-ball at several thousands of degrees temperature and, say, 10 cm. in diameter from rising under the unidirectional buoyant force of about 600 dynes.

The stability is far more likely to be fictitious, in that the discharge simply stays where the energy is available. This is what happens with a not-too-long horizontal arc in air. Relative to the fresh air moving upward into the arc (because the hot gas in the arc rises) the ionization front moves downward because the power comes from the fixed electrodes. The fireball can be expected to stay in that place relative to the Kapitza standing-wave pattern where the impedance match is best.

This raises a minor difficulty, because the ionization will start at an antinode of the electric field, but the fireball, being of low impedance compared to free space, will lie at a node. Somehow the shift has to be made and the electrical geometry of the space changed without destroying the standing-wave pattern.

A more serious difficulty for the Kapitza theory lies in the magnitude of the power required. This must be about the same as for an electric arc in air or nitrogen at one atmosphere pressure. Analysis of Cobine's Fig. 9·19 (ref. 5) gives as the relation of voltage gradient E to arc current I:

$$E = 82\, I^{-0\cdot 57} \text{ (V./cm., amp.)}$$

His Table 9·12 gives a current density of 6 amp./cm.^{2}. The surface area S of the arc per cm. of arc length therefore increases only as $\sqrt{I}$, in fact:

$$S = 1\cdot 45\, I^{0\cdot 5} \text{ (cm., amp.)}$$

Thus, the power dissipation per unit surface area is:

$$\frac{EI}{S} = 57\, I^{-0\cdot 07} \approx 57 \text{ watts/cm.}^2$$

Application of this to a fireball 10 cm. in diameter, presumably maintained by a 40-cm. Kapitza wave, yields a required power of 18 kW.

Suppose Nature to be an obliging wench faced now by the necessity of substantiating at least some of the all-too-human accounts of ball lightning; How could she proceed? First, she would recognize that she cannot use St. Elmo's fire as a stand-in, for we have learned to discriminate. Second, since the onset of the phenomenon must only alter the wave pattern a little and not react strongly on the power source, she must have about four times 18, or 72 kW., as a cushion. She will, therefore, have to generate about 90 kW. of short-wave power. At least twice this amount of primary power will be required. Third, to conform to some eye-witness testimony regarding the distance that lightning balls can be from other objects, she will have to be able to maintain the ball at a distance of some 400 cm., more or less, from conducting objects. This is ten 40-cm. wave-lengths, so that the frequency will have to be constant to a fraction of 10 per cent, say to 2 per cent. Of course she could arrange for a general background of powerful short-wave radio noise which, augmented locally by a weaker Kapitza standing-wave, could feed a fireball, but the over-all energy requirements would be greater.

She would have to design the wave-guide-system reflectors and lenses, which would focus the energy into a small volume at some distant (4 m.) point, and she would have to buy the klystrons or magnetrons and power amplifiers to put out 90 kW. for some 20 sec. of continuous operation.

This is not beyond our own capabilities, and we have the advantage of more suitable energy sources. A lightning stroke may discharge about 20 coulombs at 5×10^8 V. (ref. 6)—an energy of 10^4 MW.sec. In 20 sec. the fireball itself consumes only 0·36 MW.sec. The capacitance associated with the store of lightning energy is $3\cdot 6 \times 10^4$ cm., which would be the radius of an isolated conducting sphere bearing the 20 coulombs. This is a reasonable size for a cloud. Actually, the charge forms a dipole in the cloud, but we shall probably not make an order-of-magnitude error if we calculate the energy density as if the energy were uniformly distributed through a sphere of $3\cdot 6 \times 10^4$ cm. radius. We thus find $5\cdot 1 \times 10^{-11}$ MW.sec. cm.$^{-3}$. In the fireball it is $6\cdot 8 \times 10^{-4}$ MW.sec. cm.$^{-3}$, that is, the energy is $1\cdot 3 \times 10^7$ times as concentrated. Nature does not surpass this degree of augmentation even in the return lightning stroke, despite its being catastrophic. For her to do it over an interval of 20 sec. is another matter.

It seems highly probable that with 90 kW. of 40-cm. continuous-wave power a globular hot plasma floating in air can be formed and maintained by suitably focusing the radiation. Something along this line may, it seems, be contemplated[3], although it is to be noted that 50 kW. is the maximum power of commercial radio broadcasting stations in the United States. Some advantage could be gained by trying for a smaller fireball. A successful experiment will not, however, demonstrate the existence of Nature's own ball lightning. It would only show that, as in many cases, Nature, as both co-operator and frustrator, permits man to do it.

Absorption of Ultra-violet and Visible Light by Ultra-thin Sections of Vitrinite from a High-volatile Bituminous Coal

IT is a commonly held view that coals contain aromatic structures and that they become more graphite-like with increase in rank. X-ray studies have tended to confirm this concept; however, recent work[1] has shown that small (about 100 atoms or less) aromatic and tetrahedral structures that have comparable numbers of atoms give rise to overlapping X-ray diffraction patterns in the angular regions of the (10), (11) and (20) reflexions of graphite-like layers. The question of distinguishing between the two types of structures will have to be resolved eventually by rigorous and more detailed X-ray or electron diffraction studies. Knowledge of other physical and chemical properties would be of great help in such structural analyses. It has been reported[2] that the extinction coefficients of a high-volatile *A* bituminous vitrinite in ultra-violet and visible light are too low to admit of an appreciable content of condensed aromatic structures. A detailed study of absorption became possible when we succeeded in cutting ultra-thin sections of coals of various ranks and in accurately measuring their thickness and refractive index by interferometry[3].

The ultra-thin sections of vitrinites were obtained by cutting on a microtome, using a diamond knife. The fragments were very small; in most instances the areas suitable for accurate absorption measurements were less than 800μ in diameter. Consequently, a very intense source of light, a 1,000-watt mercury-xenon arc lamp, was used. The light was passed through a grating monochromator and then a prism monochromator to obtain high purity before passing through the specimen. This was found to be necessary to minimize the effect of fluorescence. After traversing the sample, the beam was further monochromatized by reflexion from a precision grating before intensity measurements were made by a multiplier phototube sensitive in the ultra-violet and visible.

Because of the fluctuating brightness pattern of the lamp, it was found necessary to compare the transmission through the specimen mounted on an aperture with that of an identical aperture placed in the same position. Before mounting the specimen, transmission of the two apertures was compared throughout the spectral range of interest at different slit openings to assure that they were placed in the same position. The ultra-thin specimen, mounted on a quartz plate, was arranged over one aperture, using a microscope, and an equivalent clear quartz plate fastened over the reference aperture. The quartz plate in front of the specimen reduced reflexion losses. Relative transmission readings of the two mounts in the same position were then made at the different wave-length settings. In choosing the latter, emission peaks of the lamp above the continuum were used where possible so that minimum slit openings, as low as 0·001 mm., corresponding to a resolution of 0·02 Å., could be used. For readings in the continuum, slit openings ranged from 0·01 to 0·1 mm., usually less than 0·05 mm. Transmission of the reference aperture was measured before and after that of the specimen.

Following the absorption measurements, the thickness of the specimen was measured with an *AO* Baker interference microscope. Phase retardations were measured for the specimen immersed in both air and an immersion oil to permit simultaneous determinations of refractive index and thickness. However, these parameters are not readily calculated for absorbing materials by the interference microscope. The extinction coefficient k, refractive index n, and thickness t are all involved in the solution of the phase-change equation on transmission through an absorbing material; the product kt is obtained from the absorption measurements after slight corrections for reflexion. The calculations are made by a trial-and-error procedure or graphically. This technique will be more fully described elsewhere.

Spectral absorption results have been completed for vitrinite from Pittsburgh bed high-volatile *A* bituminous coal. The thickness of the ultra-thin section used was 550 ± 20 Å., and the refractive index at 5460 Å. was 1·80. The latter value compares favourably with 1·78 found by reflectance measurements on polished blocks[4]. Variations of the specific extinction coefficient of Pittsburgh vitrinite with wave-length are shown in Fig. 1. The coefficient is defined by $K = 10^8 (\log I_0/I)/td$, where the intensity falls from I_0 to I after traversing thickness t (Å.), and d is the density (gm./cm.^{3}). The extinction coefficient, a more fundamental measure of absorp-

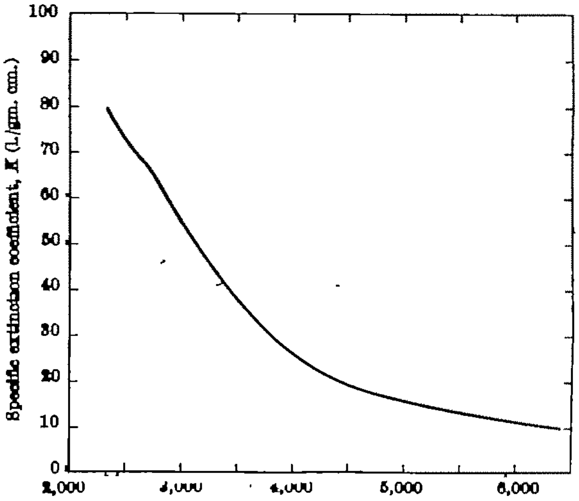

Fig. 1. Specific extinction coefficient of an ultra-thin section of vitrinite as a function of wave-length in the ultra-violet and visible. (High-volatile *A* bituminous coal, Pittsburgh bed-section, 550 Å. thick)

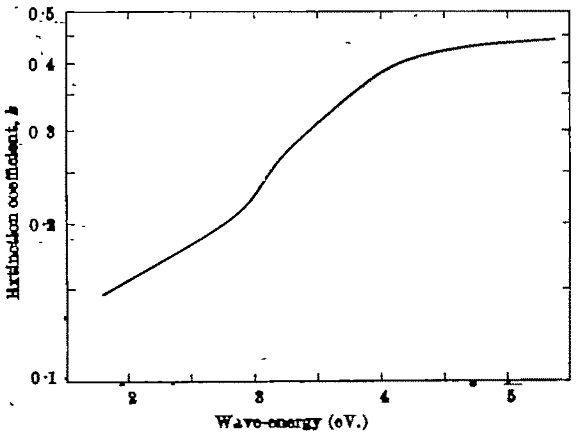

Fig. 2. Extinction-coefficient of an ultra-thin section of vitrinite as a function of wave-energy in the ultra-violet and visible. (High-volatile *A* bituminous coal, Pittsburgh bed-section, 550 Å. thick)

tion, is defined at wave-length λ_0' by $k = \lambda_0 \ln(I_0/I)/4\pi t$, and is equal to the product of refractive index and absorption index. Extinction coefficients for the Pittsburgh vitrinite are shown in Fig. 2 as a function of wave-energy and wave-length.

Ultra-violet and visible light cause the excitation of π electrons and free electron pairs. The electronic excitation is usually accompanied by the excitation of vibrational transitions, and hence absorption bands instead of lines are obtained when solids are examined. Figs. 1 and 2 show that the Pittsburgh vitrinite absorbs a considerable amount of light in the ultra-violet and visible regions. The absorption observed here is larger than that reported for a pyridine extract (in pyridine solution) of the same vitrinite[5]. The larger absorption appears to be reasonable when it is considered that the extract contained more hydrogen, and probably was composed of less-complex molecules than the vitrinite itself. Comparison of the above absorption with those of aromatic compounds indicates that the vitrinite studied contained major amounts of condensed aromatic structures.

High absorption by this coal in the visible region seems noteworthy. It may be caused by presence of structures similar to highly conjugated compounds containing oxygen or to polymerization of polycyclic hydrocarbon structures of 1–5 condensed rings. For example, rubicene, which may be regarded as a polymer of two benzene and one anthracene molecules, absorbs intensely in the red, indeed more than dinaphthocoronene, a ten-ring compound. The long wave-length edge of absorption, denoted by $A_{1g} \rightarrow B_{2u}$ in group theory notation, occurs at 2600 Å. in benzene and shifts progressively toward the red as the number of rings in the molecule increases[6].

The extinction coefficients obtained by Friedel and Queiser[2] for the Pittsburgh vitrinite are 3–4 times lower than those found here. These workers used hand-ground sections probably 3–5-μ thick on the average. We have attempted to prepare ground sections a few microns thick that would be suitable for accurate absorption measurements, but so far have been highly uncertain of effective thickness owing to the presence of very thin areas, scratches or holes in such sections. The possibility was considered that a 'skin' effect resulting from oxidation of the surfaces cut might exist and result in increased absorption. Identical extinction coefficients were obtained when another section of this coal 1060 Å. thick was employed. Furthermore, for other coals, thicknesses ranging from 500 to 1500 Å. had no influence on extinction coefficients, and identical refractive indexes were obtained for 500–1500 Å. and 1–2-μ thick sections. Therefore, it appears that such a 'skin' effect is not significant.

The present absorption results are not inconsistent with earlier X-ray diffraction results[7]. When analysed on the basis that the diffraction peaks at high angles were produced by two-dimensional reflexions of aromatic structures, the X-ray patterns showed that the average layer size was 7·0 Å., corresponding to 3–5 condensed rings. However, vacuum distillation of this vitrinite produced a distillate and residue showing X-ray patterns corresponding to a layer size of 5·8 Å. (1–3 rings)[7]. If the larger layers of the untreated vitrinite result from coplanar coalescence of smaller units or consist of imperfect larger aromatic structures, this vitrinite may be considered a polymer of small, partially oriented condensed aromatic units. However, an authentic analysis of aromatic and tetrahedral structures in coal will await more rigorous and detailed X-ray studies.

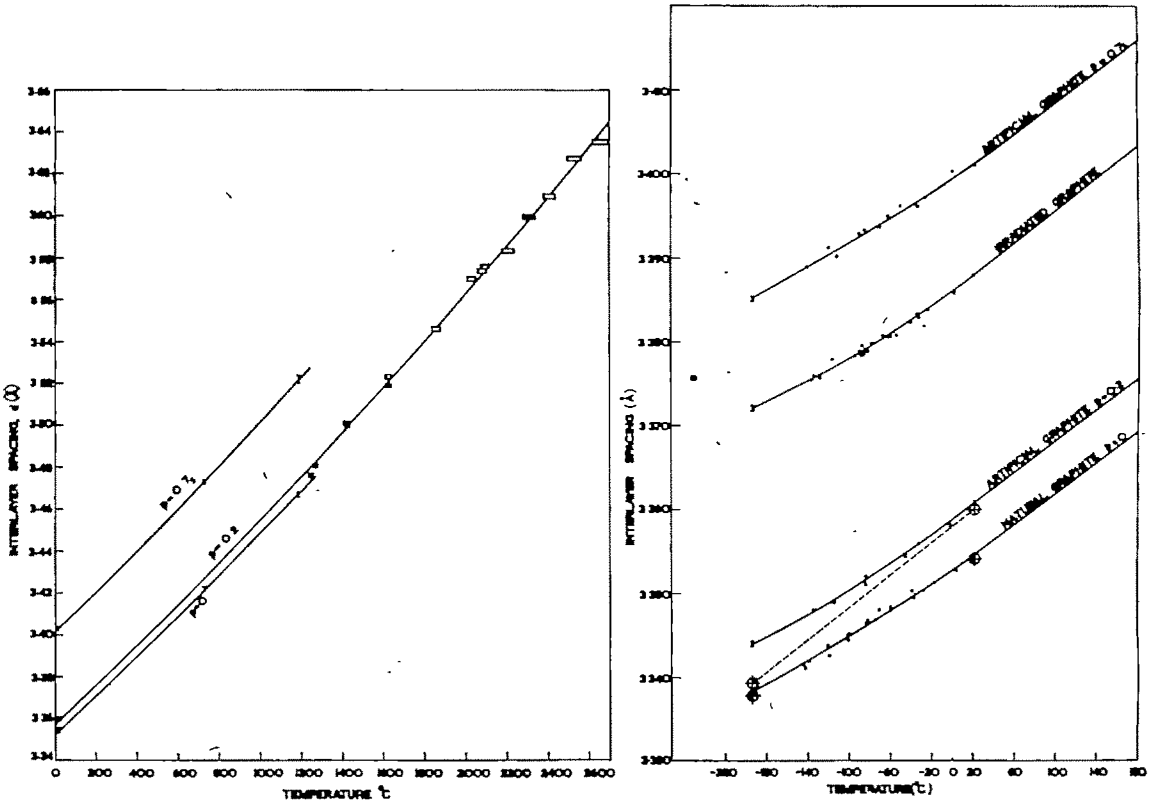
Dependence on Temperature of the Interlayer Spacing in Carbons of Different Graphitic Perfection

IN a previous communication[1], attention was directed to important inconsistencies and gaps in the literature concerning thermal expansion in graphitic carbons perpendicular to the hexagonal layer-planes. Preliminary experiments were reported, and, while these clarified the picture to some extent, the need for further experiments at higher (above 1,200° C.) and lower (below 20° C.) temperatures was indicated. Special diffractometer techniques required for these measurements have now been developed and will be described elsewhere: meanwhile, the extended results are reported.

In Fig. 1*a* measurements made at temperatures up to 2,600° C. are given for a material having a p value (the proportion of disoriented layers) of 0·2. This now clearly establishes a non-linear relationship between interlayer-spacing d (Å.) and temperature t (° C.): the empirical equation over the range 0°–2,600° C. (for $p = 0{\cdot}2$) is $d = 3{\cdot}357 + 91{\cdot}9 \times 10^{-6}\, t + 5{\cdot}3 \times 10^{-9}\, t^2$. For $p = 0$ and $p = 0{\cdot}7_5$, measurements[1] up to 1,188° C. indicate essentially similar curves translated parallel to the temperature axis, and it would seem that while the rate of expansion is dependent on the interlayer spacing it is not signifi-



(*a*) (*b*)

Fig. 1. Interlayer spacings at (*a*) high and (*b*) low temperatures. ⊕ denotes points due to Baskin and Meyer (ref. 3)

cantly dependent, for a given spacing, on stacking disorder.

In Fig. 1*b* measurements at temperatures down to −196° C. for materials having $p = 0$, $0 \cdot 2$ and $0 \cdot 7_1$ are shown. Also included are results for neutron-irradiated graphite having $p = 0 \cdot 2$, $d = d_1 = 3 \cdot 358$ (20° C.) Å. before irradiation, and $d = d_2 = 3 \cdot 388$ (20° C.) Å. after irradiation: with this material the small amount of irradiation produced little or no change in p as assessed from modulation of *hk* bands, while interstitials resulted in the increase in the average interlayer spacing[2]. The results in Fig. 1*b* give experimental support to the suggestion made previously[1] that for carbons of different graphitic perfection there will be different limiting distances of closest approach between the layers, with decreasing temperature. For $p = 0$, while the interlayer spacing at −196° C. agrees with that reported by Baskin and Meyer[3], the present results show the expected[1] gradual 'levelling-off' rather than the abrupt change in slope implied by those investigators: for $p = 0 \cdot 2$ a 'levelling-off' is again in evidence and the limiting spacing appears to be larger than that found by Baskin and Meyer. Results for $p = 0 \cdot 7_1$ are seen to be consistent with the general picture. With *n*-irradiated graphite, the results are interesting in that the interstitials, which have caused a certain increase in interlayer spacing (from d_1 to d_2) without deterioration in perfection of layer-stacking ($p = 0 \cdot 2$), have had essentially the same effect on the low-temperature behaviour as the greater stacking disorder of an unirradiated less-graphitic carbon ($p = 0 \cdot 6$) having the larger interlayer spacing (d_2).

Consideration of the family of curves for varying perfection over the extended temperature-range (−196° to 2,600° C.) shows that, while the high-temperature behaviour is controlled mainly by the interlayer spacing alone, low-temperature rate of expansion for a given spacing becomes dependent on imperfections and stacking disorder effects.

By adding a term to the quadratic equation given above for the range 0–2,600° C., it is possible to describe both the low- and high-temperature data by a single expression. For example, a term of the type $\frac{A}{(t+B)^n}$, with n a reasonably large number, gives the 'levelling-off' at low temperature and leaves the high-temperature behaviour still essentially described by the original quadratic. Curves for different p values are then derived by using the known (room-temperature) d–p relationships[4].

Further work should include consideration of the lattice dynamics.

We are pleased to acknowledge the assistance of Mr. M. W. Taylor in obtaining these results.

RADIOPHYSICS

Ionospheric Information from Satellite Signals

THE observation of radio signals from Earth satellites has opened up a new field of investigation for the examination of the ionosphere, particularly above the height of maximum ion concentration. The simplest features to observe are the fading-rate of signals resulting from the different phase paths of the ordinary and extraordinary rays, and the Doppler frequency shift.

To derive ionospheric information from a record of a single satellite transit requires very accurate observations and rather involved calculations, and the results derived in this way confirm the notorious variability of the ionosphere in both time and space.

Where an adequate series of observations is available, however, much useful information can be obtained very simply from the fading-rate. This rate, often referred to, rather loosely, as the 'Faraday fading' rate, is essentially a measure of the total ionization in the path from satellite to receiver. If a mean value is derived at the time of nearest approach, most of the minor variations are sufficiently smoothed out and even the transverse propagation dip[1] can be neglected except in low latitudes. The rate is not critical, as the Doppler shift is, of the closeness of the transit to overhead, so that a series of records over a few days can be used to obtain mean values. Moreover, in a consistent series of observations, it is possible to obtain a significant fading-rate even when much of the pattern is distorted by irregularities and diffuseness which, in themselves, are useful indications of ionospheric anomalies.

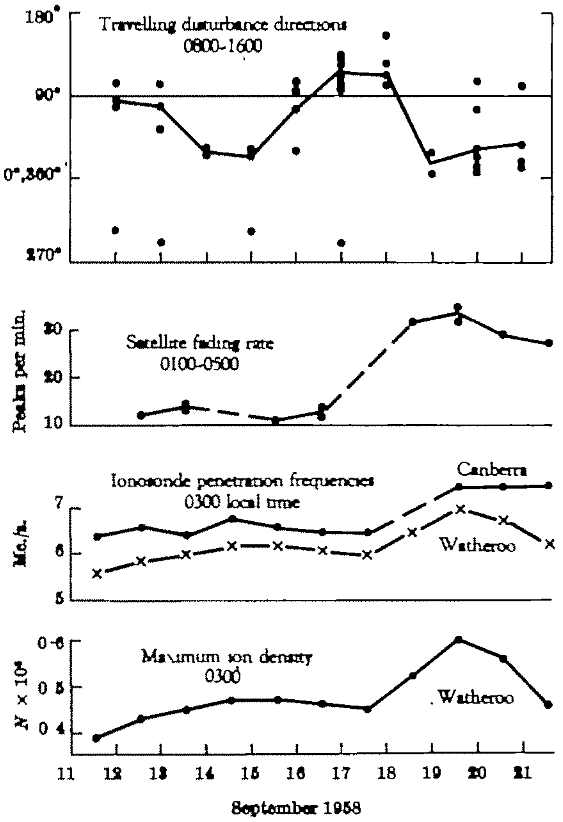

Fig. 2. Ionization changes during September 1958

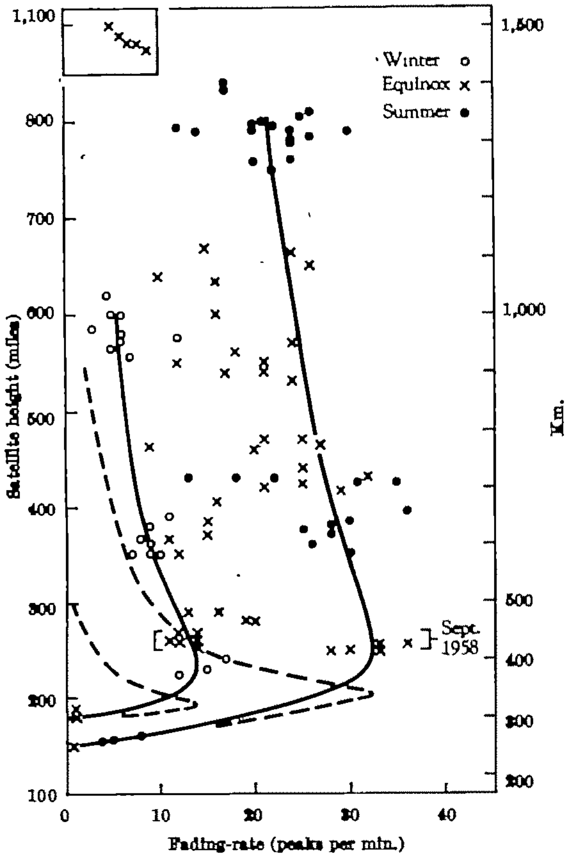

Fig. 1. Satellite signal fading-rates, June 1958–July 1960, 0100–0500

It is thus possible from regular observations at different times and heights to build up mean 'fading-rate profiles' for any particular observing site. These can then readily be converted to ionization profiles by comparison with corresponding ionosonde recordings, and deviations and their causes can then be studied.

Results derived in this way from two years observations of signals in the 20 Mc./s. band from the satellites *Sputnik III* (1958 Delta 1), *Explorer VII* (1959 Iota 1) and *Sputnik IV* (1960 Epsilon 1) are shown in Fig. 1 plotted as fades per minute against satellite height. Nearest approach times were obtained from Doppler shift records taken simultaneously by a method previously described[2]. Each point plotted represents the mean rate for a particular transit. These observations are for the period 0100–0500 local time when no direct solar influence is present and the decay in ionization is slow. The most obvious feature is the difference between the summer and winter distributions, and different symbols have accordingly been used for summer (November–January), winter (May–July) and the other months classed as equinoctial. Mean fading-rate curves are shown as full lines and the corresponding ionization profiles for summer and winter derived from them graphically in arbitrary units are indicated as dotted lines. The ratio of the summer and winter maxima of ionization is in good agreement with that obtained from ionosonde data.

The features so far mentioned will be dealt with in detail in future papers, and the main purpose of this communication is to report the remarkable result in September 1958 when the rate increased practically from winter to summer values within two days when the satellite was at a height of approximately 400 km.

An abrupt seasonal change in the ionosphere at this time of the year has been known for many years and has been consistently observed in travelling disturbance studies[3]. An examination of the available records for September 1958 did indeed show a marked change in direction of movement at this time, and also a correspondingly marked rise in critical frequency at Australian ionosonde stations. These results are shown in Fig. 2. There are some gaps in the data, but the conclusion is clear. It appears that the directional change occurred first, followed a day later by the change in rate, with the critical frequency change becoming obvious a day later again. Some fluctuation in direction after the main seasonal change is usual.

This sequence suggests a major change in the movement of ionization at this epoch which appears to be consistent with a reversal of the north–south seasonal component of drift indicated by travelling disturbances. Since this change occurred during the Geophysical Year, examination of records at other sites should yield interesting information. A magnetic storm of world-wide incidence but short duration occurred about this time, and its relation to the general change is being examined.

These results indicate the value of simple satellite observations, as a supplement to ionosonde recordings, for ionospheric studies and predictions. The 20 Mc./s. frequency band seems very satisfactory and an orbit such as that of *Explorer VII* is particularly suitable. Its height-range is 350–670 miles and this is swept through every 50 days in each transit at any site. The type of transmission used—continuous-wave with frequency modulation—is also satisfactory. The pulsed transmissions from *Sputnik III* made counting difficult at high rates, but short closely spaced pulses, as used in part of the coding of *Sputnik IV*, would be satisfactory and would enable study of multiple paths. Occasional breaks would be useful also for this purpose and for comparison of spaced receiver records. Telemetry information could also be conveyed as at present.

Observations of 'Whistlers' and 'Chorus' at the South Pole

WHISTLERS and chorus are now being observed at the South Geographic Pole (79° geomagnetic), and the seasonal and diurnal variations in occurrence of these phenomena at this unique location follow interesting and perhaps significant patterns.

Maximum chorus activity occurred during the midsummer period, gradually diminished through February and March, and virtually disappeared when the Sun dropped below the horizon. Despite this seasonal dependence on solar zenith angle, there was a surprising and considerable diurnal variation in both strength and occurrence of chorus with a consistent maximum between 1500 and 1600 U.T. corresponding to approximately 1000 hr. local magnetic time.

No whistlers were apparent during the summer period, and it was not until March 8 that the first whistler was heard. Whistlers became quite prevalent after sunset, and the rate of occurrence increased through April and May to reach a maximum during the winter solstice. A considerable and consistent diurnal variation is apparent with maximum activity centred about 0630 U.T.

Although detailed characteristics of these polar whistlers cannot be determined until the tape recordings are available for spectrographic analyses, aural monitoring indicates that they generally resemble whistlers at lower latitudes. Pure tones, swishes and multiples are most common. Echo trains with about 2½ sec. delay between events were heard on May 10 and May 31. The rate of occurrence at Pole Station (averaging 2–3 per min. during active periods) is comparable with typical whistler-rates at middle-latitude stations.

Judging from the observed characteristics of these polar whistlers, it appears that they could have been produced at lower latitudes, reaching the receiver by reflexion between the Earth and lower ionosphere[1,2]. The seasonal and diurnal variations in the occurrence of whistlers at the South Pole may therefore be due to the seasonal and diurnal variations in *D* region absorption over the path of propagation. Assuming that the whistlers are propagated more readily along the path of least absorption, the diurnal peak at 0600 U.T. at Pole Station suggests that the whistlers penetrate the ionosphere somewhere along the 70° meridian, probably in the vicinity of Graham Land, approximately 55° south geomagnetic latitude. In middle latitudes whistler-rates are generally higher at night and in local winter, and therefore consistent with the hypothesis that *D* region absorption affects whistler propagation. If this interpretation is correct, coincidence should exist between whistler occurrences at South Pole Station and Port Lockroy. This will be investigated when the recordings from both stations are available for analyses.

The origin, or origins, of chorus are not fully understood. The seasonal variation of this phenomenon at the South Pole, with maximum activity occurring in midsummer, suggests direct dependence on solar radiation. It seems probable, therefore, that the polar chorus signals are initiated by solar corpuscular radiation impinging on the outer ionosphere.

The association between very-low-frequency hiss and aurora observed at Byrd Station, Antarctica, is also apparent at Pole Station[3]. However, whereas the auroral hiss observed at Byrd Station usually centres about a frequency of 8 kc./s., at Pole Station, 10° higher in geomagnetic latitude, the auroral hiss centres about 9·5 kc./s. This change in frequency of aurora-associated hiss with latitude is interesting. At 42° south geomagnetic Ellis[4] has associated very-low-frequency noise at 4–6 kc./s. with aurora, and current investigations also indicate that the frequency of aurora-associated hiss may decrease with geomagnetic latitude.

The very-low-frequency observations at Pole Station are being made by Oliver C. Morse of the United States Antarctic Research Program. The

work reported in this communication is supported by National Science Foundation Grant G-9511.

GEOLOGY

Olivine–Spinel Transition on Nickel Orthosilicate

The pressure-induced transition of olivine to a denser spinel structure is probably of considerable importance in the Earth's mantle[1]. Olivine–spinel transitions are known in Mg_2GeO_4 (refs. 2 and 3) and Fe_2SiO_4 (ref. 1), while a variety of evidence indicates that Mg_2SiO_4 will undergo a similar transition around 125,000 atmospheres and 600° C. (refs. 1 and 3). These results suggested the desirability of exploring for olivine–spinel transitions in other substances which normally crystallize with an olivine structure.

Such a substance is nickel orthosilicate—Ni_2SiO_4. From preliminary[1] and recent (Ringwood, A. E., unpublished results) data on the solid solubility of Ni_2SiO_4 in Ni_2GeO_4 (spinel) and vice versa, I have calculated that Ni_2SiO_4 should undergo an olivine–spinel transition around 54,000 atmospheres at 1,500° C. However, Wentorf[4] has recently reported unsuccessful attempts to synthesize a spinel modification of Ni_2SiO_4 at pressures up to 110,000 atmospheres. I have carried out further high-pressure experiments using a uniaxial pressure apparatus (squeezer), in an attempt to resolve the conflict, and provide further information on olivine–spinel transitions.

Intimate mixtures of $Ni(OH)_2$ and silicic acid in orthosilicate ratios were prepared, and subjected to pressures between 0 and 50,000 atmospheres, at 650° C., for periods between 1 and 6 hr. Fourteen runs were made. After completion of a run, the pressure was rapidly released, while the sample was quenched and then examined by X-ray diffraction.

At pressures below 15,000 atmospheres the phases observed were Ni_2SiO_4 olivine, NiO, and nickel talc. It may be shown that the last two products constitute a metastable assemblage, due to incomplete reaction. Above 20,000 atmospheres, olivine disappeared and in its place a spinel phase appeared, together with NiO and talc. Between 15,000 and 20,000 atmospheres, spinel, olivine, talc and NiO appeared simultaneously. A run at 50,000 atmospheres, using a mix containing 20 per cent excess $Ni(OH)_2$ over that required to form the normal orthosilicate, produced spinel and NiO. Talc was absent.

A sample of Ni_2SiO_4 olivine was prepared by sintering a tablet of intimately mixed NiO and SiO_2 at 1,400° C. for 6 hr. The tablet was then crushed, reformed and resintered, this procedure being repeated twice. A sample thus prepared was subjected to 50,000 atmospheres and 700° C. for 2½ hr. About 80 per cent conversion to the spinel form was observed. Similar runs were carried out at 30,000 and 20,000 atmospheres. A small amount of spinel formed at 20,000 atmospheres, but curiously, no spinel formed at 30,000 atmospheres.

Mixtures of silicic acid, hydrous germanium dioxide, and nickel hydroxide were prepared at intervals in the composition range between Ni_2GeO_4 and Ni_2SiO_4. These were run at 33,000 atmospheres and 650° C. A complete series of spinel solid solutions was found to exist between Ni_2GeO_4 (normally a spinel) and Ni_2SiO_4. The solid solutions obeyed Vegard's law.

It is concluded that the new phase is the spinel modification of Ni_2SiO_4 and that the equilibrium pressure for the olivine–spinel transition in Ni_2SiO_4 at 650° C. is about 18,000 atmospheres. Ni_2SiO_4 spinel is green, transparent, and has a lattice parameter of 8·044 Å. The calculated density is 5·34 gm./c.c., which is about 9 per cent higher than that of the olivine modification.

The experimental transition pressure is in good agreement with the value calculated (54,000 atm.) from zero pressure equilibria at 1,500° C. in the system $Ni_2GeO_4 - Ni_2SiO_4$ if a reasonable allowance is made for the effect of temperature on transition pressure. A detailed description of equilibria in this system, and the calculations based upon it, will be published elsewhere.

Wentorf's failure to synthesize Ni_2SiO_4 spinel at much higher pressures than I used may be due to the different type of apparatus employed[4]. We both used mixtures of $Ni(OH)_2$ and silicic acid as starting materials, and operated at temperatures sufficiently high to cause the components to react and form Ni_2SiO_4. However, the uniaxial device which I used permits rapid quenching—in particular, the water vapour pressure can be instantaneously released. Published descriptions[5] suggest that Wentorf's apparatus may not have been able to quench the reaction products as quickly; furthermore, the quenching may be carried out in the presence of a high pressure of water vapour (from the pyrophyllite pressure medium). Thus it is possible that any spinel formed at high pressures afterwards became inverted to olivine during the quench.

Potassium–Argon Ages of Some Rocks from the South Atlantic

The ages of micas separated from a number of rocks from the South Orkney Islands have been determined using the potassium–argon method.

In these particular measurements, the total volume of argon evolved on fusion of the samples was measured by means of a McLeod gauge, and a correction applied for atmospheric contamination using a mass spectrometer to resolve the argon isotopes. Potassium analyses were made with a flame photometer.

All the rocks measured were quartz–mica–schists[1], eight from Signy Island and one from Moe Island nearby (composite sample contains Moe Island material *H*.1365.1). Analytical results and calculated ages are given in Table 1.

Table 1

Mineral	Ref. No.	Weight of sample (gm.)	K_2O (per cent)	Total argon (mm³)	Approximate age (m. yr.)
Biotite	*H*. 60.3	6.6570	4.22	0.177	176
Biotite	*H*. 86.1	12.0716	7.51	0.625	199
Biotite	*H*. 154.8	14.3500	8.38	0.877	188
Biotite	*H*. 164.2	7.3086	4.75	0.226	184
Biotite	*H*. 205.2	8.9206	5.13	0.323	195
Biotite	*H*. 507.3	6.2023	4.00	0.181	195
Muscovite	*H*. 507.3	6.9700	6.38	0.306	176
Biotite	*H*. 1,369.1	6.2587	4.12	0.173	189
Biotite	*H*. 1,365.1 *H*. 1,384.1	7.3328	6.23	0.39	193

$\lambda_\beta = 4.76 \times 10^{-10}$ yr.$^{-1}$. $\lambda_e = 0.585 \times 10^{-10}$ yr.$^{-1}$.

Errors in the results arise from inaccurate measurement of the volume, in the estimation of potassium, or in measuring the argon-40/argon-36 ratio. In these measurements, a 1 per cent error in either the proportion of potassium oxide or the volume of radiogenic argon would result in a 1 per cent error in the age. The errors introduced in correcting for atmospheric contamination may be neglected. The total error of measurement is estimated to be less than ± 5 per cent.

The similarity between all the ages so far measured suggests that argon has not been released by recent weathering. They indicate a Lower-Jurassic–Upper-Triassic age[2] (Jurassic 135 ± 5 to 180 ± 5 m. yr., Triassic 180 ± 5 to 225 ± 5 m. yr.) either for the original metamorphism of the schists or for some subsequent metamorphism sufficiently intense to have released their radiogenic argon. The basement schists in the South Orkney Islands are overlain by intensely folded greywackes thought to be of carboniferous age[3], and by slightly folded conglomerates of Mesozoic age[4]. Results from the potassium–argon work are consistent with the hypothesis that radiogenic argon already present was released from the schists during the orogeny which folded the overlying greywackes. No mineralogical evidence of retrograde metamorphism of the schists of Signy Island has been reported.

Thanks are due to the Falkland Islands Dependencies Survey and Dr. R. J. Adie for providing the specimens used in this work, from their collection at the University of Birmingham, and to the Department of Scientific and Industrial Research for financing this work. I am indebted to D. H. Matthews of the Department of Geodesy and Geophysics, Cambridge, for suggesting to me the problem and its geological interpretation.

Age of the Cambrian System

RECENT contributions by Wetherill[1] and Holmes[2] lay stress upon studies of the brannerite (so-called 'absite') from Crocker Well, South Australia, as affording critical evidence on the age of the base of the Cambrian System, but dispute the interpretation of the various results (in the range 520–915 million years) arrived at in dating this mineral. The publication of this discussion prompts me to report why these data from South Australia were ignored, as being irrelevant, in my own notes on the geological time-scale[3]. My conclusions were arrived at in the light of a first-hand knowledge of the Australian deposits, which I visited some years ago, and arose from the following considerations.

(1) Statements that the brannerite occurrences are overlain by Precambrian sediments of the Adelaide System are incorrect. The nearest sediments are six or seven miles away[4]. In these Precambrian strata, pebbles of granite are found which are akin to the adamellite forming the country-rock of the mineral deposits—but this in no way helps to fix the stratigraphical age of the brannerite unless this mineral can be shown to be contemporary with the country-rock.

(2) The samples of brannerite for which isotopic assays are available were not collected specifically for geochronological study with full records of paragenesis, but were presumably supplied out of a stock of concentrate from prospecting operations. It is thus not known whether they were derived from "porous shear zones", as claimed by some authors, or from the tight, breccia-like, stockworks of quartz veins which have formed the main source of the mineral. All the brannerite is amorphous due to metamictization. Consequently there is no geological basis for the several divergent hypotheses, postulating loss of radon due to rock porosity, or retention of radon due to well-defined crystallinity, adduced in argument about the discordant ages.

(3) In addition to brannerite the deposits also contain davidite, the two uraniferous titanates often being intimately intergrown. Greenhalgh and Jeffery[5] have shown that a specimen of this davidite, with an age of 1,600–1,700 m.y., is more than twice as old as the brannerite analysed.

(4) Throughout the whole Olary province, there are a great many occurrences of uranium mineralization (nearly all quite small), and the few that have been analysed isotopically show a wide range of ages. The oldest mineralization is roughly coeval with the great lead deposit of Broken Hill nearby. Both at Crocker Well and Radium Hill, primary uranium minerals bearing at least two widely divergent ages occur in a single ore deposit. In such cases it seems reasonable to attribute the younger datings to re-working, not necessarily as a result of late granitization but probably arising as a simple regeneration *in situ* in response to local tectonic conditions. Comparable regeneration is apparent in the Hercynian pitchblende deposits of Western Europe[6] and in many other uranium fields.

(5) There is no evidence that the latest period of regeneration at Crocker Well is Precambrian in age. Within the province there are many post-Proterozoic mineral veins cutting the strata of the Adelaide System, and the last re-working could be coeval with these lodes. The potassium : argon age of 520

m.y. reported by Greenhalgh and Jeffery[5] relates not to a biotite "hand-picked from the rock", as stated by Wetherill, but to a biotite "hand-picked from the brannerite". The two minerals occur intergrown in nests and may well have been re-constituted contemporaneously.

If these interpretations are correct, the brannerite mineralization is completely lacking in stratigraphical definition and contributes no information about Cambrian chronology. The dating of the base of the Cambrian System at about 600 ± 20 m.y., founded on other evidence, remains unassailed.

CHEMISTRY

A Molecular Complex of Benzene and Hexafluorobenzene

In the course of experiments using mixtures of benzene and hexafluorobenzene, it was observed that a solid was formed on mixing these two substances although this frequently disappeared before the mixing process was complete. This observation has been followed up by the investigation of the freezing points, obtained from cooling curves, of mixtures of known composition of benzene and hexafluorobenzene.

The freezing-point diagram shows two eutectic points occurring at mole fractions of 0·15 and 0·85 of hexafluorobenzene, and melting at about 0·5° C. and −5·5° C. respectively. The diagram shows a maximum melting point of 23·7° C. corresponding to a mixture containing equimolar quantities of the two substances. Benzene and hexafluorobenzene have similar melting points (5·4° C. and 5·0° C. respectively). This clearly demonstrates the formation of a 1 : 1 molecular complex of the two compounds. Less-complete freezing-point diagrams have been obtained for the systems hexafluorobenzene and fluorobenzene, and pentafluorobenzene and benzene. The first of these shows evidence of the formation of a 1 : 1 complex of hexafluorobenzene and fluorobenzene melting at about −3° C., that is, above the melting point of fluorobenzene but below that of hexafluorobenzene. No solid complex appears to be formed between pentafluorobenzene and benzene. The complexes seem to be similar to that formed as a low-melting white solid on mixing aniline and hexafluorobenzene[1].

These complexes may be regarded as examples of the Lewis base–Lewis acid (electron donor-acceptor) or charge-transfer type, of which those between picric acid and a number of aromatic compounds, and between, for example, benzene and *sym*-trinitrobenzene[2], are familiar examples. Fluorine atoms show a strong negative inductive effect which is reflected by the observation that the ionization potentials of polyfluorobenzenes are higher than that of benzene[3], and by the behaviour of polyfluorobenzenes in chemical reactions. In showing a negative inductive effect, the fluorine atom resembles the nitro group, and it is likely that the conditions in polynitrobenzenes which favour the formation of complexes will also occur in polyfluorobenzenes. The substitution of groups showing a positive inductive effect in the 'basic' partners of the complexes should increase the stability of the complexes with hexafluorobenzene. A complex, melting at 34°, has been prepared from hexafluorobenzene and mesitylene. This complex, unlike that between hexafluorobenzene and benzene, is sufficiently stable to allow its crystallization from ether. A similar complex, melting at 56° C., has been obtained between hexafluorobenzene and 2-methylnaphthalene, and this also is sufficiently stable to allow its crystallization from ether.

Complexes of this type are generally characterized by a charge transfer spectrum. In the expectation that a transfer spectrum such as that observed (in the region 2800–3400 Å.) in the case of the complex between benzene and *sym*-trinitrobenzene would be found, a preliminary investigation has been made of the spectra of neat mixtures of benzene and hexafluorobenzene. No absorption band has been found in the region 2900–4000 Å., where the two liquids do not themselves absorb light. The spectra of mixtures of the two compounds have been measured in the region 2300–3000 Å. using ethanol and hexane as solvents. No absorption bands were observed other than those due to benzene and hexafluorobenzene, but it is probable that the concentrations used were too small to allow the formation of significant concentrations of the complex.

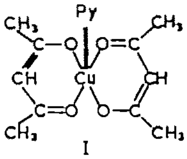
Structure of the 1 : 1-Adducts of Cupric β-Diketone Chelates with Heterocyclic Bases

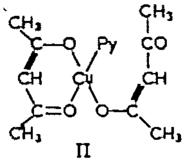
In a recent communication, Traill[1] raises the question of the structure of the 1 : 1-adducts formed by cupric β-diketone chelates with heterocyclic bases in organic solvents[2]. The same question has been raised privately by others, and it seemed, therefore, that we should seek some further evidence in support of the 5 : co-ordinated structure (I) originally proposed as against the 4 : co-ordinated structure (II) suggested by Traill.

The original attribution of structure I to these adducts was essentially intuitive, and as their low stability makes isolation improbable, a definitive structure determination seems unattainable. We believe, however, that the weight of available evidence strongly favours structure (I).

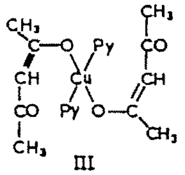
(1) The stability of acetylacetonates and related compounds is largely due to chelation. If reaction



I



II



III

with heterocyclic bases may result in the opening of a chelate ring, it is difficult to see why only one ring should be opened, giving (II) rather than both rings giving (III), or even complete displacement giving salts of the type $[Cu(C_5H_5N)_4]^{2+}$ 2(acac)⁻.

(2) Replacement of an oxygen donor by a heterocyclic base normally results in a shift of ligand-field bands to shorter wave-lengths. In this case the shift is very slightly to longer wave-length, an effect paralleled by co-ordination of a fifth ammonia molecule to the $[Cu(NH_3)_4]^{2+}$ ion[3] and in other cases of extension of formally 4 : co-ordinated species to 5 : co-ordination.

(3) Gaussian analysis of the absorption spectra of cupric ethyl-acetoacetate in solvents which do not form adducts shows that the broad absorption band in the visible region consists of two bands with maxima about 550 mμ and 710 mμ; but when the heterocyclic base adducts are formed, the band at 550 mμ disappears and a new band appears at about 900 mμ. Such drastic changes in the ligand-field absorption would not be explicable if the adduct had structure (II), in which the environment of the copper atom is fundamentally unchanged, but is consistent with the formulation of the adducts as 5 : co-ordinated species[4].

(4) In seeking further evidence for the structure of these adducts, we have now examined the infra-red absorption of *M*/40 chloroform solutions of cupric acetylacetonate and cupric ethyl-acetoacetate, and of the same solutions containing *M*/2 γ-picoline (chosen because it gives more complete adduct formation with the minimum concentration of heterocyclic base—under these conditions adduct formation is about 90 per cent complete). In the region 1,500–1,620 cm.⁻¹, metal β-diketone chelates show two very strong absorption bands, which are characteristic of the chelate ring system, as they do not appear in keto or enol forms of the free β-diketones or in acetyl-acetone acetate[5]. Opening of one of the two chelate rings to give (II) should thus be accompanied by a halving of the intensities of these bands. These bands are reported in the acetylacetonates of chromium-(II) and chromium-(III) (ref. 6) at 1,567–9 cm.⁻¹ and 1,517–8 cm.⁻¹ and of cerium-(III) (ref. 7) at 1,562 and 1,510 cm.⁻¹. In our complexes they are observed as follows:

	ν_1	ε_1	ν_2	ε_2
Cupric acetylacetonate	1,577	380	1,525	530
Cupric acetylacetonate/picoline	1,577	460	1,525	500
Cupric ethyl-acetoacetate	1,597	525	1,522	675
Cupric ethyl-acetoacetate/picoline	1,597	475	1,522	600

where ε is the extinction per mole of β-diketone.

While the accuracy of the extinctions is not high, due to heavy background absorption by the heterocyclic base, it is apparent that they remain almost unchanged, as required for structure (I).

Catalytic Racemization of *tris*(Ethylenediamine)Cobalt(III) Ion

ALTHOUGH the optical isomers of the *tris*(ethylene-diamine)cobalt(III) ion, ($[Coen_3]^{3+}$), are stable indefinitely in aqueous solution at 100° C., complete racemization can be effected at 90° C. in 2 min. in the presence of activated carbon[1]. It has been proposed that racemization is a surface phenomenon, and no decomposition of the complex cation occurs[1]. More recently[2], the isomerization of lævo-*tris*(*l*-propylenediamine)cobalt(III) ion to the equilibrium mixture of the *d* and *l* forms of the complex cation was carried out with activated carbon in aqueous solution at 20° C. in 15 min. These reactions are obviously of the same nature as the rapid equilibration of mixtures of cobalt(III) complexes in various preparative procedures[3,4] brought about by activated carbon, for which no satisfactory explanation has yet been proposed.

We have found, after treatment in aqueous solution with activated carbon, cobalt(III) complexes in general, for example, *tris*(acetylacetone)cobalt(III), *tris*(glycine)cobalt(III), hexammine cobalt(III) ion, *tris*(oxalato)cobaltate(III) ion, invariably contain small amounts of cobalt(II) complexes. The amounts of the latter have been found to depend on the temperature, time of contact with, and the nature of the carbon, as well as the presence or absence of oxygen or air.

In a typical experiment, a solution (10 ml.) containing *d*-*tris*(ethylenediamine)cobalt(III) chloride (0·2 gm.) and activated carbon (B.D.H. gas-absorption) was boiled for 3 min. The optically inactive solution, after removal of the carbon, was made acid with sulphuric acid. The Co^{2+} ion, estimated with triphenylmethylarsonium thiocyanate[5], was found to be 4·2 per cent of the total cobalt. Under the same conditions, but in sulphuric acid (0·1 *N*), the rotation decreased by only 6 per cent, but substantially the same amount of Co^{2+} ion was found (4·0 per cent). Schwarz and Kronig, who first used charcoal as a catalyst in cobalt(III) complex equilibria, failed to detect any cobalt(II) complex or salt, and subsequent workers have overlooked the reducing properties of charcoal.

These observations suggest electron-transfer racemization proceeding through the labile $[Coen_3]^{2+}$ ion, which is decomposed by acid. The carbon appears to serve three functions: (*a*) as a catalyst for the conversion of a small amount of the spin-paired $[Coen_3]^{3+}$ ion to the activated spin-free paramagnetic state which it then (*b*) reduces to the spin-free $[Coen_3]^{2+}$

ion, and (c) as a catalyst for the electron transfer process:

$$d[\mathrm{Coen}_3]^{3+}\ \text{spin-paired} + l[\mathrm{Coen}_3]^{2+}\ \text{spin-free} \rightarrow l[\mathrm{Coen}_3]^{3+} + d[\mathrm{Coen}_3]^{2+} \rightleftharpoons l[\mathrm{Coen}_3]^{2+}$$

Activated carbon is known to be capable of effecting mild reductions in aqueous solution, for example, ferric to ferrous ion, but would not be expected to reduce the spin-paired [Coen$_3$]$^{3+}$ ion because of the negative potential of couple [Coen$_3$]$^{3+}$ spin-paired/[Coen$_3$]$^{2+}$ spin-free ($E_0 = -0·232$ V.)[3]. The potential of the couple [Coen$_3$]$^{3+}$ spin-free/[Coen$_3$]$^{2+}$ spin-free, in which both oxidation states are electronically equivalent, would be expected to be very much more positive.

Because of electronic non-equivalence, electron transfer between cobalt(II) and cobalt(III) complexes in aqueous solution is usually slow[6]. For example, the complete electron-transfer racemization of d[Coen$_3$]Cl$_3$ (0·0551 M) in the presence of d,l-[Coen$_3$]SO$_4$ (0·02 M) and ethylenediamine (0·24 M) in a nitrogen atmosphere at 25° C. required 8 days[7]. Activated carbon (2 gm. in 100 ml. of solution) catalysed the above reaction strongly, and all activity was lost in 2 min. at 25° C.

Racemization was also catalysed by freshly prepared platinum, palladium and rhodium black, and small amounts of cobalt(II) complex could be detected. In the presence of these metals a reducing agent was necessary. This could be adsorbed hydrogen, sulphite ion or even alcohol.

'Eddy' Diffusion in Chromatography

UNDER the above title, J. Calvin Giddings[1] has discussed the axial spreading of the solute in chromatographic columns which is responsible for the smearing of zones and in particular the contribution made to this by 'eddy' diffusion.

In 'eddy' diffusion the spreading of the solute is less than could be derived from random walk considerations applied to the carrier fluid, since the uneven velocity distribution causes radial concentration gradients, which by radial molecular diffusion tend to keep the solute closer together in the axial direction.

For turbulent flow in unpacked tubes the appropriate theory has been worked out by Taylor[2]. The velocity distribution in laminar flow also produces a spreading effect which is counteracted by radial diffusion. This case has also been examined by Taylor[3]. A generalized treatment for tubes of arbitrary cross-section and for arbitrary velocity profiles is due to Aris[4].

In our publication[5] on the statistical treatment of mechanisms causing axial spreading we have expressed the view (*loc. cit.*, p. 267) that the velocity distribution (in this case a parabolic one) and the radial molecular diffusion cannot be considered as being statistically independent, the reason being that the second process reduces the effect of the first. Giddings (*loc. cit.*) states that the two processes are independent.

For independent processes, when variances must be added, as we have explained, both the apparent diffusion coefficient D and the height H corresponding to an ideal stage have conserved the property of additivity, since they are proportional to the variance.

However, in order to obtain a reduction in D (or H), Giddings has introduced the additivity in a factor n occurring in the denominator in his equation (1) on the strength of a statement that n is the sum of numbers of steps for the two supposedly independent processes. We fail to see the statistical justification for this procedure.

The fact that, for proper a and b, the form:

$$1 \Big/ \left(\frac{1}{a} + \frac{1}{b}\right)$$

has the correct limits for $b \rightarrow \infty$ and $a \rightarrow \infty$ is of course insufficient to justify the treatment.

VARIANCES add[1], for certain independent processes which, by virtue of an elementary random event, contribute directly to the variance. Lateral diffusion is not such a process. The variance is caused by non-equilibrium established by the difference in downstream velocity from point to point. Lateral diffusion acts to reduce this variance as can be seen by the inverse relationship between variance or plate height and diffusion coefficient. The random change in velocity which occurs along a given stream path, as found in packed columns but not in capillary columns, also reduces the variance. Both factors act independently to exchange molecules between fast- and slow-moving regions.

The fact that independent processes do not necessarily contribute additive terms to the variance can be seen by use of a simple example which, unlike the above, can be accounted for in an exact fashion. Let the transition between two discrete species, A_1 and A_2, with downstream velocities v_1 and v_2 occur by two independent mechanisms. The forward and reverse rate constant for the first mechanism are k_1 and k_2, respectively, and for the second mechanism, k_1' and k_2'.

Using a method developed elsewhere[2] for obtaining asymptotic expressions for plate height with complex kinetics, we obtain:

$$H = \frac{2R\,(1-R)\,(v_1 - v_2)}{k_2 + k_2'}$$

where R, the ratio of average solute to average fluid velocity, is an equilibrium property. Rate effects appear only in the denominator, and, in fact, are additive in the denominator as proposed for eddy diffusion[3]. We see that "the second process reduces the effect of the first"[1], but the processes are, none the less, physically independent. This fact in no way depends upon having a single-step mechanism. If solute molecules are shuttled laterally by two independent diffusion processes, it can be shown[1], as expected, that the diffusion coefficients add in the denominator, one reducing the effect of the other. In close analogy with eddy diffusion, both diffusion processes "act independently to exchange molecules between fast- and slow-moving regions". It is, in fact, possible to assign an effective coefficient of lateral diffusion (even though lateral diffusion, as such, is not necessarily involved) to describe the effect of velocity variations along a streamline. A close analysis of this shows that the effective diffusion coefficient varies with the distance across the interstice while the molecular diffusion coefficient is constant[4]. At any point these two are additive in the denominator, but the addition of the averages of the two, and this is essentially what was done in the earlier treatment[3], is an approximation. I am at present looking for an improvement of the admittedly approximate derivation previously given.

BIOCHEMISTRY

Exclusion of Inulin from Solutions of Hyaluronic Acid

THE partition of inulin between buffer and solutions containing hyaluronic acid has been observed by dialysing inulin to equilibrium between the two solutions. 'Millipore *HA*' membranes were used which are readily permeable to inulin but impermeable to hyaluronic acid. The hyaluronic acid was prepared from ox synovial fluid by the method of Ogston and Stanier[1]; inulin was Kerfoot biochemical reagent twice 'recrystallized' from dilute ammonia.

The partition depended on the concentration of hyaluronic acid according to $\log K = 2w$, where K is the ratio of concentration of inulin in buffer to that in the hyaluronic acid solution at equilibrium and w is the weight of hyaluronic acid/100 ml. The partition was independent of the concentration of inulin, the direction of equilibration, *p*H and ionic strength. Thus at $w = 0{\cdot}2$, $K = 2{\cdot}5$, and this can be thought of as the exclusion of inulin from 60 per cent of the volume of the hyaluronic acid solution. These results have a bearing on the use of inulin for determining the volumes of tissue spaces.

The effect is not peculiar to inulin, but is shown by other carbohydrates and by proteins, to degrees depending on their effective molecular volumes; this suggests that the mechanism of exclusion is steric.

Alkaline C-1 Fructose-1,6-diphosphatase: Evidence for its Participation in Photosynthesis

PATHWAYS proposed for the conversion of carbon dioxide to hexose monophosphate during photosynthesis require the cleavage of the phosphate linked to carbon-1 of either fructose-1,6-diphosphate, or sedoheptulose-1,7-diphosphate, or both[1–3]. A C-1 alkaline phosphatase specific for fructose-1,6-diphosphate has been prepared from spinach leaves and characterized by Racker and Schroeder[3]. This enzyme was not thought to participate in photosynthesis since it did not appear to be localized in the chloroplasts. Recently it was reported[4] that pea chloroplasts isolated in various aqueous media lost about 90 per cent of their ribulose-1,5-diphosphate carboxylase, an enzyme considered to play an essential part in photosynthesis[1]. Since this finding indicated that photosynthetic enzymes were not necessarily retained in chloroplasts isolated by the usual procedures, the possible function and intracellular distribution of alkaline fructose-1,6-diphosphatase in photosynthetic tissues were re-investigated.

A survey of a number of plants and bacteria disclosed that alkaline fructose-1,6-diphosphatase was widely distributed in photosynthetic tissues. In addition to spinach[3] and pea[4] leaves, alkaline fructose-1,6-diphosphatase has been demonstrated in cell-free extracts of photosynthetic tissues from barley, alfalfa, *Spirodela*, the fern *Pteris gautheri*, the algae *Euglena gracilis* and *Chlamydomonas reinhardii*, and the photosynthetic bacteria *Rhodospirillum rubrum* and *Chromatium*. Conversely, the enzyme was not found in extracts of pea root or an apoplastidic strain (streptomycin-bleached) of *Euglena gracilis*. The activity of the enzyme in etiolated pea leaves was less than 5 per cent of the maximum activity found in green pea leaves. In related work in which quantitative measurements were made of the levels of various enzymes in growing pea leaves, it was observed that the alkaline fructose-1,6-diphosphatase activity of the leaf followed a pattern of development similar to that previously ascertained for a number of photosynthetic enzymes[4]. The above evidence attests to a close correspondence between alkaline fructose-1,6-diphosphatase and chloroplast development and function.

Intracellular distribution studies of cell particulates isolated in either 0·5 *M* sucrose or 0·35 *M* sodium chloride were inconclusive because of the apparent loss of most of the photosynthetic enzymes from the chloroplasts during the fractionation procedure. However, this work did show that a small amount of

Table 1. THE DISTRIBUTION OF ALKALINE FRUCTOSE-1,6-DIPHOSPHATASE IN PEA LEAF AND *Euglena* FRACTIONS ISOLATED IN NON-AQUEOUS MEDIA

Plant material	Density of isolated fraction	Fructose-1,6-diphosphatase*	
		Per cent activity in fractions	Activity per chlorophyll (μmoles P/min./mgm. chlorophyll)
Pea leaf	<1·34	68	0·52
	1·34–1·40	28	0·57
	>1·40	4	0·56
Autotrophic *Euglena*	<1·29	88	0·32
	1·29–1·36	9	0·57
	>1·36	3	0·57

* The reaction mixture contained *tris*(hydroxymethyl)aminomethane buffer, *p*H 8·5 (100 μmoles/ml.), fructose-1,6-diphosphate (8·5 μmoles/ml.), magnesium chloride (5 μmoles/ml.), and ethylenediamine tetraacetate (1·5 μmoles).

the total cellular alkaline fructose-1,6-diphosphatase was retained in the chloroplasts to an extent equivalent to that reported previously for ribulose-1,5-diphosphate carboxylase[4]. Furthermore, the specific activity of the enzyme in the chloroplast fraction was higher than in the other fractions. More informative results were obtained from experiments in which fractionations of pea leaves and *Euglena* cells were carried out in non-aqueous media. The procedure detailed by Stocking[7] for spinach leaves was followed, except that the *Euglena* cells were broken by grinding with glass beads (0·1–0·25 mm. diameter) with a pestle and mortar. This fractionation procedure produced an enrichment of chloroplast material in the low-density fractions[4,7]. The results in Table 1 show that the majority of the alkaline fructose-1,6-diphosphatase activity was associated with the lightest fractions and that the activities in the various fractions closely followed the distribution of chlorophyll. The low value for the activity of fructose-1,6-diphosphatase expressed on a chlorophyll basis in the *Euglena* fraction less dense than 1·29 was accounted for by the presence in this fraction of unbroken *Euglena* cells. Separate experiments showed that no significant amounts of protein were released from unbroken cells during the fractionation procedure. These distribution studies suggest that the alkaline fructose-1,6-diphosphatase of pea leaf and *Euglena* is localized in the chloroplasts.

Although it has been shown that leaf extracts also contain an acid fructose-1,6-diphosphatase[3], no evidence has been obtained to implicate this enzyme in photosynthesis. The developmental studies and intracellular distribution experiments indicated that the leaf acid fructose-1,6-diphosphatase did not participate directly in photosynthesis, nor was it localized in chloroplasts. Extracts of *Chromatium*, an obligate anaerobe and phototroph, contained only the alkaline fructose-1,6-diphosphatase.

On the basis of the observations mentioned above, it is suggested that alkaline fructose-1,6-diphosphatase constitutes an integral part of the enzymic mechanism for the photosynthetic conversion of carbon dioxide to carbohydrates.

This investigation was carried out at Brookhaven National Laboratory under the auspices of the U.S. Atomic Energy Commission.

Transiodination of Proteins during Enzymic De-iodination of Thyroxine

DURING the enzymic de-iodination of thyroxine labelled with iodine-131, triiodothyronine and related compounds with tissue homogenates, a fraction of the radioactivity consistently appeared in a material of $R_F = 0$ in various chromatographic systems[1]. The amount of 'origin' radioactive material found on chromatograms increased almost in parallel with the de-iodination of the substrate. With the identification of ferrous ions and flavin as activators for thyroxine dehalogenase[2], the formation of this material was found to be dependent only on flavin derivatives. The nature of the 'origin' iodine-131 labelled material was studied with purified preparations of thyroxine dehalogenase[3]; it was found to be radioiodinated protein(s) present in the tissue enzymic extracts, as described below.

L-Thyroxine labelled with iodine-131 was incubated at 37° with thyroxine dehalogenase prepared from rabbit skeletal muscle, at *p*H 7·1 (ref. 3). The radioactive products of the reaction were analysed by paper chromatography and electrophoresis. Full experimental details have been described elsewhere[4]. Next to iodide, the material of $R_F = 0$ was the only other major labelled product formed. As shown in Fig. 1, the rate of formation of iodide was only slightly diminished in the absence of flavin mononucleotide in a ferrous ion-activated enzyme system, whereas the formation of radioactive 'origin' material was almost abolished.

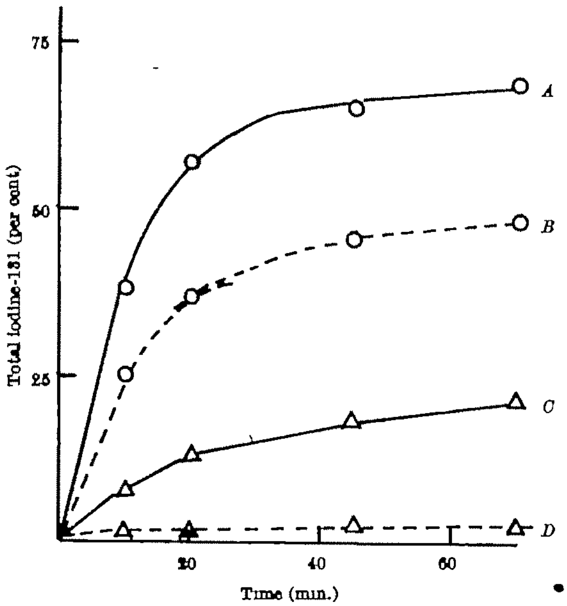

Fig. 1. Formation of radioactive iodide (○) and 'origin' material (△) as the principal products of enzymic de-iodination of thyroxine labelled with iodine-131 by rabbit skeletal muscle thyroxine dehalogenase as measured by chromatographic analysis. Each flask contained in 2·5 ml. *tris*-hydrochloric acid – potassium chloride buffer[3], *p*H 7·1, 5·0 μmoles of L-thyroxine, 12 mgm. of enzyme of × 72 purification. Additions: *A* and *C*, 0·035 μmole ferrous ion and 0·1 μmole flavin mononucleotide; *B* and *D*, 0·035 μmole ferrous ion alone

After incubation of labelled thyroxine with a fully activated enzyme, the 'origin' material was separated by paper chromatography. It was non-dialysable and precipitated with trichloroacetic acid; it was then digested with crude trypsin or pancreatin. The hydrolysate on chromatographic analysis was found to contain most of the iodine-131 as 3-iodo-tyrosine with traces of 3 : 5-diiodotyrosine, which suggested the presence of iodinated proteins.

In order to confirm that proteins were iodinated with the iodine released from thyroxine, extraneous proteins were added in relatively large amounts to the muscle enzyme extract. Insulin and egg-white lysozyme were most suitable because of the ease of distinguishing from muscle proteins by electrophoresis and their feeble thyroxine-binding activity (thyroxine

Table 1. IODINATION OF INSULIN AND EGG-WHITE LYSOZYME PRESENT DURING INCUBATION OF ^{131}I-LABELLED L-THYROXINE (T_4) WITH RABBIT SKELETAL MUSCLE THYROXINE DEHALOGENASE

None	—	83·6	15·1	—
Insulin	2·0	72·7	22·0	50·2
	5·0	60·0	28·7	68·5
Lysozyme	2·0	74·4	18·2	31·8
	5·0	70·1	24·5	43·6

Conditions identical to those in Fig. 1. Enzyme fully activated with ferrous ions and flavin mononucleotide.

dehalogenase can only attack 'free' substrate). Both these proteins were readily radioiodinated in the presence of radioactive thyroxine and the enzyme (Table 1), and on tryptic hydrolysis after separation by paper electrophoresis gave rise to labelled monoiodotyrosine. Since free iodotyrosines were not a product of action of dehalogenase, the transfer of iodine atoms from thyroxine to the tyrosyl radicals of added proteins represents a true process of transiodination.

Observations reported elsewhere[2] have suggested that the iodination of proteins is not a secondary process of a flavin-mediated oxidation of the iodide released by the dehalogenase but rather a direct substitution. It was proposed that the contribution of the flavin was to release part of the iodine atoms at a level of oxidation necessary for iodination under conditions of incubation. It should be noted that the fraction of thyroxine iodine available for tyrosyl substitution was twice the fraction of protein-bound iodine-131 shown in Fig. 1 or Table 1 according to R.H. + 2I^{+} → R.I. + R.I.

Since enzymic dehalogenation of thyroxine is not a peroxidative process[3], the iodination of proteins reported here does not resemble the 'transiodination' of some iodotyrosines and iodothyronines with peroxidase[4].

The physiological significance of transiodination of proteins coupled to a de-iodination of thyroid hormones, which had hitherto remained unnoticed, remains doubtful. Considering the extremely high ratio of proteins to thyroxine in tissues, it would be difficult to demonstrate such a transiodination *in vivo*.

Stabilization by Manganous Ions of Ribosomes from Embryonic Plant Tissue

PREPARATIONS of microsomal ribonucleoprotein (ribosomes[1]) from sources such as yeast, pea shoots, rat liver and clover leaves have been shown to consist largely of particles with sedimentation coefficient approximately 70 *S* (refs. 2–5). These particles are stable when dialysed against solutions containing magnesium ions at concentrations between 1 and 2 m*M*; but removal of magnesium by dialysis or addition of chelating agents leads to dissociation of the 70 *S* particles with production of sub-units of sedimentation coefficients 50 *S* and 30 *S*. By contrast, I have found with ribosomes from wheat germ that in order to preserve intact 70 *S* particles on dialysis, manganese and calcium are required in addition to magnesium in the dialysing solution.

Wheat germ was blended for 2 min. with four times its weight of a solution containing 5 m*M* magnesium chloride, 2 m*M* calcium chloride, and 0·025 *M* *tris*(hydroxymethyl)ammomethane/hydrochloric acid (*tris*) buffer at *p*H 7·3. The ribosomes were isolated by two stages of fractional centrifugation in the same buffered medium[3]. The material thus obtained was homogeneous on examination in the analytical ultracentrifuge, and contained only the 70 *S* component (Fig. 1*a*).

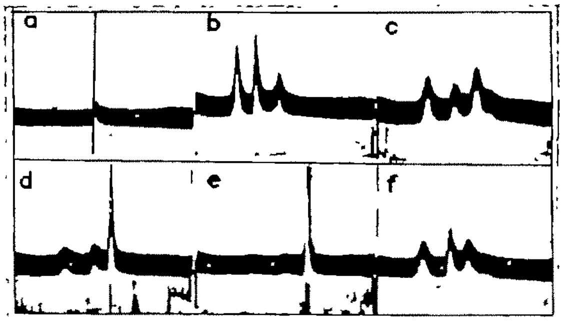

Fig. 1. Ultracentrifuge diagrams of wheat germ ribosomes: *a*, as prepared in 0·025 *M* *tris*, 5 m*M* magnesium sulphate, 2 m*M* calcium chloride; *b*, dialysed v. 0·025 *M* *tris*, 1 m*M* magnesium sulphate; *c*, dialysed v. 0·025 *M* *tris*, 2 m*M* magnesium sulphate; *d*, dialysed v. 0·025 *M* *tris*, 1 m*M* magnesium sulphate, 0·2 m*M* manganous chloride; *e*, dialysed v. 0·025 *M* *tris*, 1 m*M* magnesium sulphate, 0·2 m*M* manganous chloride, 0·5 m*M* calcium chloride; *f*, dialysed v. 0·025 *M* *tris*, 1 m*M* magnesium sulphate, 0·2 m*M* nickel sulphate. All solutions at *p*H 7·3. Ribosome concentration: *a*, 10 mgm./ml., *b*–*f*, 5 mgm./ml. All photographs taken after 9 min. at 42,000 r.p.m. Sedimentation left to right

In order to test the stability of these ribosomes under different conditions, 1·0-ml. samples at a concentration of about 5 mgm./ml. were dialysed against three changes of 300 ml. of the test solution for 24-hr. periods. The dialysed sample was then examined in the ultracentrifuge.

It will be seen from Fig. 1 that dialysis against a buffer containing 1·0 m*M* magnesium sulphate led to almost complete dissociation of the 70 *S* particles, and increasing the concentration to 2·0 m*M* was only partially effective in counteracting this dissociation. Dialysis against higher concentrations of magnesium led to production of aggregated material. When 0·2 m*M* manganous chloride was added to the 1·0 m*M* magnesium, however, the dissociation was largely suppressed. Increasing the manganese concentration to 0·5 m*M* further repressed the dissociation, but the most effective medium for preserving the 70 *S* particles intact on dialysis has been found to be a *tris* buffer containing 1·0 m*M* magnesium sulphate, 0·2 m*M* manganous chloride and 0·5 m*M* calcium chloride (Fig. 1*e*). In the presence of manganese, the effect of calcium was specific. Increasing the magnesium concentration did not have the same effect. In the absence of magnesium or calcium, complete dissociation of the 70 *S* particles was not prevented by addition of manganese to 0·5 m*M* concentration.

Similar concentrations of divalent salts of nickel, cobalt, iron, zinc and copper were all closely similar; and all much less effective than manganese in stabilizing the 70 *S* particles (Fig. 1*f*).

We have also observed a similar stabilizing effect of manganous ions on ribosomes prepared from pea seeds.

Analysis of wheat germ ribosomes for manganese[6] gave values of 0·12–0·14 μgm. per mgm. ribonucleic acid. The extract from which they were isolated contained approximately ten times as much manganese per mgm. ribonucleic acid.

This dissociation of 70 *S* particles on dialysis in the presence of magnesium is in contrast to the reported behaviour of ribosomes prepared from the sources referred to earlier[2-4]. A further difference exhibited by wheat germ ribosomes is the irreversibility of the dissociation which occurs on dialysis either in the presence or absence of magnesium. Further dialysis of the dissociated particles against the buffer containing magnesium, manganese and calcium, which was effective in repressing dissociation, led to aggregation of the 50 *S* and 30 *S* components, but little if any 70 *S* component was regenerated.

It is possible that the difference in properties of the ribosomes studied here may be due to their having originated from embryonic rather than fully differentiated tissue. Further work will be required to check this.

The β-D-Fucosidase Activity of Mammalian Tissues and its Relation to other Glycosidases

AN earlier communication[1] described the occurrence of the enzyme α-L-fucosidase in mammalian tissues. These tissues have now been surveyed for β-D- and β-L-fucosidase activity, using the appropriate *p*-nitrophenyl fucosides as substrates. The β-D-fucoside was hydrolysed by all the mammalian tissues that were studied, and also by an extract from the limpet, *Patella vulgata*, but no β-L-fucosidase activity was detected anywhere.

Table 1 gives figures for some of the richest sources of β-D-fucosidase, alongside comparable figures for β-D-galactosidase[2]. Since fucose is 6-deoxygalactose, β-D-fucosidase could be identical with β-D-galatosidase, but the parallelism which would then be expected between the two enzyme activities, within at least a single species, was not observed. Inhibition experiments with the appropriate aldonolactones[3] are shown in Table 2. While the results for the preparations from the rat are consistent with the action of a single enzyme, with a higher affinity for the galactose than for the fucose residue, the figures for ox liver suggest the very opposite. In any event, the enzyme or enzymes in the two species are evidently quite different. This is reflected in differences I have observed in the *p*H-activity curves.

Whether or not it is due to β-D-galactosidase, the β-D-fucosidase activity of mammalian tissues is considerable. D-fucose has not been reported in animals, but both D- and L-fucose occur in plants. Although L-fucose has been positively identified in mammalian preparations in at least two instances, in other cases its presence has been inferred from evidence that does not distinguish it from the D-enantiomorph. As with other galactose derivatives, the biological interconversion of D- and L-fucose by an end-to-end oxidation-reduction would appear to be feasible.

Table 1. β-D-FUCOSIDASE AND β-D-GALACTOSIDASE ACTIVITIES OF MAMMALIAN TISSUES

	β-D-Fucosidase			β-D-Galactosidase		
	Pig	Ox	Rat	Pig	Ox	Rat

Kidney	31,700	1,010	4,050	28,550	1,860	11,400
Epididymis	360	900	3,300	970	1,740	47,300

Results expressed as μgm. *p*-nitrophenol (fucosidase) or *o*-nitrophenol (galactosidase) liberated per gm. moist tissue in 1 hr. at 37°.

Table 2. INHIBITION OF β-D-FUCOSIDASE AND β-D-GALACTOSIDASE BY D-ALDONOLACTONES

Source of enzyme	β-D-Fucosidase Fucono-lactone	Galactono-lactone	β-D-Galactosidase Fucono-lactone	Galactono-lactone
Rat epididymis	0	56	0	60
Rat liver	0	64	0	65
Ox liver	0	0	32	0

The experiments were done at *p*H 4 in 0·05 *M* acetate buffer with 1 m*M* substrate and inhibitor. Results are expressed as inhibition per cent.

One interesting observation made in this work was a great variation in the β-D-fucosidase activity of cow ovary, which was found to be related to the amount of luteal tissue present. The corpus luteum had a mean activity of 1,000 units per gm., whereas the remainder of the tissue had only one-tenth of this activity and the enzyme was virtually absent from the follicular fluid. This phenomenon was shown to extend to α-L-fucosidase, β-D-galactosidase, α-D-mannosidase, β-D-glucuronidase and β-*N*-acetyl-D-glucosaminidase in cow ovary. While the physiological significance of these results is obscure, they point to a common function for all six enzymes, and to direct or indirect control of their activity by the anterior pituitary. As already shown for the other four enzymes[4], β-D- and α-L-fucosidase in epididymis and uterus respond to castration by steep falls in activity.

Grateful acknowledgment is made to Dr. J. Conchie for help with some of the enzyme assays, and to Mr. A. McAllan for skilled technical assistance.

Biosynthesis of Squalene by the Annelid *Lumbricus terrestris*

LARGE amounts of sterols have been shown to be present in many of the invertebrates, although cholesterol does not seem to occur predominantly among the more primitive animals. Instead, as Bergmann has pointed out, the lower phyla especially appear to contain a diverse group of sterols with structures which are more similar to those of plants[1]. Moreover, since some Protozoa and insects have been shown to require dietary cholesterol[2], it has been suggested that the invertebrates cannot synthesize their own sterols, but rather modify the steroid nucleus present in their food sources.

Mevalonic acid, isolated as a growth factor for a strain of *Lactobacillus acidophilus*[3], has been shown to be a precursor of squalene and cholesterol with *in vivo* experiments using the rat[4], and in isolated mammalian[5,6] and yeast systems[7]. The extent of mevalonic acid utilization by invertebrate animals is now being studied to determine by isolation and identification of radioactive components of the non-saponifiable fraction what genetic blocks exist in various phyla.

A species from the phylum Annelida has been found to convert mevalonic acid to squalene, but is incapable of cyclizing the hydrocarbon. Specimens of *Lumbricus terrestris* were placed in moist cellulose powder which contained 0·1 per cent 'Moldex' and 10,000 units penicillin (Lilly) and were allowed to burrow in this medium for six days to remove symbionts undoubtedly present in the alimentary canal. Additional penicillin solutions were added on the second and fourth days, and the worms averaging 6–8 in. long and 3–4 gm. in weight remained quite lively. Potato agar plates streaked with coelomic fluid from a treated worm showed only a few small, slow-growing colonies of *Clostridium* sp. The mevalonic acid solution contained penicillin and aureomycin and was always injected into the coelomic cavity.

In one experiment, 11 animals were administered 6 μm. 2-^{14}C mevalonic acid (Tracerlab) with a total activity of 700,000 counts/min. Twenty-four hr. later they were homogenized in a Waring blendor with water in a nitrogen atmosphere prior to four extractions at *p*H 11 with double volumes of petroleum ether (30–60° C.)/ethanol (9 : 1 mixture by vol.). The sodium sulphate-dried extracts were combined for solvent removal *in vacuo*, and the residue with approximately 10 per cent of the injected activity was dissolved in light petroleum ether for chromatography on an acid-washed alumina (Merck) column. After 150 ml. petroleum ether wash had passed through the column, the squalene was eluted with a 100 ml. mixture of benzene/petroleum ether (1 : 9). Solvents were removed *in vacuo* and the residue was counted on a Nuclear Chicago gas-flow counter. Eighteen mgm. squalene (Eastman Organic Chemicals), previously redistilled and purified by alumina chromatography, were added as carrier to the colourless oil, which weighed 7 mgm. and had an activity of 16,000 counts/min. The hexahydrochloride derivative, prepared according to the Heilbron method modified by Loud and Bucher[4], had a specific activity of 475 c.p.m./mgm., while a second recrystallization from acetone resulted in an increase to 630 c.p.m./mgm. Results of an elemental analysis of the squalene hexahydrochloride synthesized by this micro procedure corresponded to the theoretical percentages of carbon (57·26), hydrogen (8·92), and chlorine (33·83) (analysis by Geller Lab. carbon (57·21), hydrogen (8·85), chlorine (34·10)).

In another experiment purified carrier squalene was added to the non-saponifiable fraction obtained from another group of animals prior to separation by alumina chromatography. The squalene fraction had a specific activity of 86 c.p.m./mgm. before the derivative was made, and the activity remained relatively constant over four recrystallizations (Table 1).

Table 1. RECRYSTALLIZATION OF ^{14}C SQUALENE HEXAHYDROCHLORIDE TO CONSTANT SPECIFIC ACTIVITY

Recrystallization	Weight (mgm.)	Counts/min.	C.p.m./mgm. squalene hexahydrochloride (Corrected to infinite thinness)
1	9·7	1,820	185
2	7·6	1,112	182
3	5·6	840	176
4	5·0	767	176

The alumina column was developed further with 1 per cent acetone in petroleum ether and radioactivity was found associated with a β-carotene band. β-carotene (N.B.C. recrystallized) was added as carrier, but after crystallization it was inactive. Then several milligrams of coenzyme Q_{10} (Merck) were dissolved in an ether solution of the labelled compound and chromatographed on 'Florisil'. Though the activity moved with the carrier, on recrystallization coenzyme Q_{10} was inactive and the bulk of the carbon-14 compound was recovered in the supernatant liquid. Rechromatography on alumina with very small cuts assayed indicated that the radioactive compound moved slightly faster than the coloured component, but its identity is unknown.

Cholesterol was eluted from the alumina column with acetone/petroleum ether (1 : 1) and after removal of solvent was precipitated with 1 per cent digitonin in 80 per cent ethanol. The resulting voluminous complex was inactive. In addition, the homogenate of three animals injected with labelled mevalonic acid was subjected to saponification procedures which involved refluxing on a steam-bath for 8 hr. with 2 *N* alcoholic potassium hydroxide. Five petroleum ether extractions were made, combined, dried over sodium sulphate, and the activity measured after removal of solvent *in vacuo*. This residue with 6,200 counts/min. was dissolved in 6 ml. ethanol and 3 ml. of 1 per cent digitonin solution was added. After ethanol and ether washes 77·2 mgm. of digitonide were plated and found to be devoid of radioactivity.

Thus, the conversion of mevalonic acid to squalene has been shown to occur in the phylum Annelida. However, a genetic block on the pathway from squalene to the β-hydroxy and/or 5 αH sterols appears to exist in the species studied.

Grateful acknowledgment is made to Dr. H. A. Schneiderman for his interest and helpful suggestions.

Phosphate Esters produced by Mammalian Skin from 2-Deoxy-D-glucose

IN a recent report concerning the phosphate esters synthesized by skin maintained on various substrates *in vitro*[1] we described the formation of two phosphate esters from 2-deoxy-D-glucose which were not detected with skin maintained on D-glucose. One of these was identified as 2-deoxy-D-glucose-6-phosphate; this communication describes the identification of the second ester.

Three phosphate esters commonly formed from D-glucose-6-phosphate in living cells are D-fructose-6-phosphate, D-glucose-1-phosphate and D-gluconate-6-phosphate. 2-Deoxy-D-glucose-6-phosphate cannot, for obvious structural reasons, be converted to a product corresponding to D-fructose-6-phosphate, so it seemed likely that the unknown ester was either 2-deoxy-D-glucose-1-phosphate or 2-deoxy-D-gluconate-6-phosphate. The latter possibility was chosen for investigation since 2-deoxy-D-glucose-1-phosphate is probably unstable.

Oxidation of D-glucose-6-phosphate with bromine is known to yield D-gluconate-6-phosphate[2] so that a similar oxidation of 2-deoxy-D-glucose-6-phosphate appeared to be a suitable method for preparing 2-deoxy-D-gluconate-6-phosphate. Barium 2-deoxy-D-glucose-6-phosphate was obtained as described previously[1] by the phosphorylation of 2-deoxy-D-glucose using yeast hexokinase and adenosine triphosphate. The oxidation was carried out with bromine in aqueous solution at 40° C. for 22 hr. in the presence of sodium benzoate as a buffer. After cooling, the precipitated benzoic acid was removed by filtration, the solution aerated until colourless and treated with silver carbonate to remove bromide ions. The resultant solution was passed through an 'Amberlite *IR*-120' (H^+ form) column, concentrated under reduced pressure and extracted with chloroform to remove the remaining benzoic acid. It was then neutralized with calcium carbonate and the filtered, neutral solution freeze-dried to a white powder.

A solution of the product, converted to the sodium salt by treatment with sodium carbonate, was mixed with an extract prepared from skin slices (about 20 mgm.) previously incubated for 24 hr. at 37° C. on a medium consisting of 0·02 *M* 2-deoxy-D-glucose in Krebs–Ringer phosphate labelled with 15 μc. phosphorus-32 per ml. This mixture was subjected to two-dimensional paper chromatography and a radioautograph of the chromatogram prepared; the experimental procedure was exactly as previously described[1] with other reference compounds. The spot obtained on spraying the paper chromatogram for phosphate esters coincided exactly with the position of the unidentified spot produced on the radioautograph; the same result was obtained on repetition of the experiment. The R_I values obtained in propan-1-ol/aq. ammonia solution (sp. gr. 0·880)/water (60 : 30 : 10 by vol.) were 0·95 and 1·03; in picric acid/2-methyl propan-2-ol/water (4 : 8 : 20, w/v/v) they were 0·78 and 0·78. Therefore the product of bromine oxidation of 2-deoxy-D-glucose-6-phosphate appears to be identical to the previously unidentified phosphate ester produced by skin in the presence of 2-deoxy-D-glucose.

However, chemical investigation of the synthetic product showed that it was not calcium 2-deoxy-D-gluconate-6-phosphate. Treatment with *N*-hydrochloric acid at 100° C. for 30 min. produced no hydrolysis of the phosphate group whereas the phosphate group in 2-deoxy-D-glucose-6-phosphate is 70 per cent hydrolysed under these conditions[3]; it is unlikely that the formation of a carboxylic acid group at C(1) would decrease the acid-lability to this extent. The periodate consumption, measured spectrophotometrically[4], was 1 mole per 111 gm. compared to the calculated consumption of 1 mole per 158 gm. These properties and the elementary composition are consistent with a calcium hexonate-6-phosphate (found: C, 22·0; H, 3·7; P, 9·3; $C_6H_{10}O_{10}PCa_{1\frac{1}{2}}$ requires C, 21·6; H, 3·0; P, 9·3 per cent). Oxidation of 2-deoxy-D-glucose-6-phosphate at C(2) as well as at C(1) could lead to D-gluconate-6-phosphate or D-mannonate-6-phosphate. Comparison of the products of bromine oxidation of both D-glucose-6-phosphate and of 2-deoxy-D-glucose-6-phosphate gave indistinguishable results for periodate consumption and infra-red spectra, but on two-dimensional chromatograms different R_I values were obtained. A pure sample of D-mannonate-6-phosphate could not be obtained from D-mannose-6-phosphate; even after four days oxidation some D-mannose-6-phosphate remained. Chromatography of the reaction mixture showed a component having R_I values consistent with those obtained for the oxidation product of 2-deoxy-D-glucose-6-phosphate. As the bromine oxidation product of 2-deoxy-D-glucose-6-phosphate is indistinguishable from calcium D-gluconate-6-phosphate by periodate consumption, infra-red absorption, acid hydrolysis and elementary composition but differs chromatographically; this product is almost certainly calcium D-mannonate-6-phosphate.

Since the previously unidentified phosphate ester produced by skin from 2-deoxy-D-glucose is identical chromatographically with the product of bromine oxidation of 2-deoxy-D-glucose-6-phosphate this ester is presumably D-mannonate-6-phosphate. It seems probable that in both the chemical and the biological synthesis 2-deoxy-D-gluconate-6-phosphate is formed initially and is then immediately converted to D-mannonate-6-phosphate. The production of 2-deoxy-D-gluconate-6-phosphate by cells has not previously been reported although cell-free extracts of *Leuconostoc mesenteroides* have been found[5] to contain an enzyme which catalyses the reduction of triphosphopyridine nucleotide by 2-deoxy-D-glucose-6-phosphate. The relative intensity of blackening of the two spots on our radioautographs indicates that although D-mannonate-6-phosphate is formed, most of the 2-deoxy-D-glucose is converted only to 2-deoxy-D-glucose-6-phosphate.

An Antibiotic Complex derived from a *Streptomyces* and active against Gram-positive Bacteria

CULTURE medium in which a *Streptomyces* (Strain No. 1415 of the Montecatini collection; now listed as No. 3838 of the collection of the Institute of Microbiology, Rutgers University) had been grown was found to contain an antibiotically active complex of eight components, effective against Gram-positive bacteria.

The organism in question produced pinkish growth with a diffusible pink pigment. The spores were spherical to ovoid, and the sporophores in the form of tufts of short hyphæ with slightly curled ends.

It was capable of hydrolysing starch and decomposing gelatin and casein.

Cultures for antibiotic production were made in a medium containing (per cent w/v) 0·25 peptone, 0·25 meat extract, 1·0 glucose, 0·5 sodium chloride and 1 per cent (v/v) corn steep liquor (40 per cent solids), in a 20-litre tank at 27° C. These were grown for 72 hr., constantly stirred, and aerated with 15–20 litres/min. of air.

The medium was then filtered and extracted with ethyl acetate, the solvent dried, reduced *in vacuo* and washed in dilute sodium hydroxide. The ethyl acetate was further reduced in volume and passed through a short column of an intimate mixture of 'Darco *G* 60' and 'Hyflo-Supercel' (1 : 1). After elution with ethyl acetate and concentration, the crude complex was precipitated by petroleum ether, dissolved in hot carbon tetrachloride and passed through a similar, longer column, eluted with benzene and again precipitated by petroleum ether.

The purified complex was a white, amorphous powder, soluble in lower alcohols, acetone, chloroform and ether, insoluble in water. The percentage composition was approximately: C, 59·5; H, 8·0; N, 2·0 ($c = 1$ per cent in methanol) $[\alpha]_D^{20} = -34·5°$. In the hydrolysate, seven amino-acids were detected: glycine, proline, alanine, valine, phenylalanine, leucine and aminobutyric acid (probably the γ-isomer). The ultra-violet adsorption spectrum showed a maximum at 282 mμ.

By paper chromatography, eight components of the complex could be recognized.

The *LD*50 in albino mice was 400 mgm./kgm. intravenously, 600 mgm./kgm. intraperitoneally and 2 mgm./kgm. subcutaneously.

The complex was active against *Bacillus* spp., staphylococci and hæmolytic streptococci at 0·25 μgm./ml. or less, but was inactive against Gram-negative bacteria and non-hæmolytic streptococci.

PHYSIOLOGY

Effect of Hydration on Hexobarbitone-induced Sleep in Mice

Hydration of laboratory animals and man produces a complex picture generally indicating increased excitability of the central nervous system. This is attributed to osmotic disturbances produced by fall of the extracellular electrolytes[1]. It is therefore interesting to find in albino mice that after hydration the sensitivity of the central nervous system to hexobarbitone was increased simultaneously. This conclusion is based on the results obtained from the following experiments.

Adult albino mice received intraperitoneally hexobarbitone sodium 100 mgm./kgm. after water-load. Control mice received only hexobarbitone. In some control experiments mice received water (or normal saline or 5 per cent glucose) just after recovering from sleep (Table 1).

About 2–4 hr. before becoming absorbed, intraperitoneally administered 5 per cent glucose solution is known to remove electrolytes from the extracellular body fluid, thus producing a condition comparable to hydration[2]. Mice receiving this treatment were used ½ and 2 hr. later for hexobarbitone sleep. The effect of normal saline was also studied (Table 2).

Table 1. Effect of Hydration on Hexobarbitone Sleeping Time in Mice. Water at 37° C. injected Intraperitoneally. Animals were kept at 32–35° C.

Hydration ml. % of body-weight	Min. between hydration and hexobarb.	Sleeping time min. ± *S.D.*	No. of mice used	Value of *P* (*t* test)
Nil	Nil	21 ± 4·1	20	
5	30	18 ± 6·8	21	*
10	0	36 ± 9·5	12	< 0·01
10	15	56 ± 12·7	15	< 0·01
10	30	49 ± 11·2	20	< 0·01
10	60	40 ± 12·3	15	< 0·01
10	240	26 ± 6·8	8	< 0·05
10	Just after hexobarb. sleep	22 ± 5·5	20	

* Not significant.

Table 2. Effect of 0·9 per cent Sodium Chloride Solution or 5 per cent Glucose at 37° C., injected Intraperitoneally, on Hexobarbitone Sleeping Time in Mice. Room Temperature 32–35° C.

Fluid ml. % of body-weight	Min. between fluid and hexobarb.	Sleeping time min ± *S.D.*	No. of mice used	Value of *F* (*t* test)
10 (Glucose)	30	25 ± 5	18	< 0·02
10 (Glucose)	120	54 ± 12·9	18	< 0·01
10 (Saline)	30	22 ± 8·8	18	*
10 (Saline)	120	17 ± 8·4	12	*

* Not significant.

Results indicate that 10 per cent but not 5 per cent hydration prolongs hexobarbitone sleeping time, the maximal effect occurring 15 min. after hydration. The effect was also seen 30 and 60 min. after hydration. The rate of water excretion can explain these results. Animals recovering from sleep go back again to sleep after hydration but not after saline load. This suggests sensitization of the central nervous system and excludes other mechanisms of action. Hydrated mice were quieter but essentially normal in their behaviour. All experiments could be repeated on the same animals after 2–3 days.

Glucose solution, requiring a certain time-interval to deplete the extracellular electrolytes, produces a distinct effect 2 hr. later. Further work is in progress.

Evidence for the Identity of Natriferin, the Frog Water-Balance Principle and Arginine Vasotocin

Maetz, Morel, and Lahlouh[1] recently reported that pituitary extracts from amphibians and teleosts contain a principle which promotes the active transport of sodium by the isolated skin of the frog *Rana esculenta*. This factor cannot be oxytocin or a vasopressin since it has approximately ten times more activity on sodium transport than do mammalian extracts of similar oxytocic activity. Maetz *et al.* named this principle 'natriferin'.

Heller[2,3] first pointed out that fish, amphibian, avian, and reptilian pituitary extracts exert far more effect on frog water-balance than can be attributed to their content of oxytocin or vasopressin. Pickering and

Table 1. Relative Activities of Oxytocin, Arginine Vasopressin, Arginine Vasotocin, and a Bull-frog Neurointermediate Lobe Extract on Natriferin Assays, and on other Assays (Refs. 5, 8, 9, 12)

Preparations	Activities (μgm./mgm. dry weight)				
	Rat vasopressor	Rat uterus (no Mg^{++})	Frog bladder	Frog antidiuretic	Frog natriferic
Bullfrog neurointermediate lobe	0·52 (0·50–0·54)	0·59 (0·55–0·64)	79	190	47
Arginine vasotocin	64 (62–67)	37 (34–41)	10,000	19,000	4,400
Arginine vasopressin	300	9	70	—	70
Oxytocin	—	430	360	360	360

The figures shown in parentheses are the 95 per cent confidence limits.

Heller[4] have recently succeeded in separating the 'water-balance principle' by paper chromatography of fish, frog, and fowl pituitaries. From chromatographic and pharmacological studies on the chicken neurohypophysis Munsick *et al.*[5] conclude that this gland contains oxytocin and a peptide pharmacologically indistinguishable from arginine vasotocin (arginine[8] oxytocin). This analogue of the mammalian neurohypophysial hormones has been synthesized by Katsoyannis and du Vigneaud[6,7] and generously supplied by them for study in this Department. It has much greater activity on the water permeability of the frog bladder than any other neurohypophysial hormone or analogue that I have yet tested[8]. It is also extremely potent in causing water uptake (water-balance response) and antidiuresis in frogs[9]. I have gathered pharmacological evidence for its existence in pituitary extracts from cyclostomes, teleosts, amphibians, reptiles, and birds[10]. It is probably not present in elasmobranchs or mammals.

Natriferin has been clearly demonstrated in teleosts and amphibians, but appears to be absent in mammals and elasmobranchs[1]. The correspondence of the phyletic distributions of natriferin, the water-balance principle, and what I believe to be arginine vasotocin strongly suggests that they are identical. It is of pressing interest, therefore, to assay synthetic arginine vasotocin for 'natriferic' activity.

I have used a simplified Ussing–Zerahn[11] short-circuited frog skin for natriferic assays. An inside-out skin bag from the leg of *Rana pipiens* is suspended in a carbon dioxide–bicarbonate-buffered Ringer's solution. The bag is filled with the same solution. 'Sodium current' is measured by balancing the electromotive force across the skin and recording the applied current. Extracts and synthetic peptides are added to the bath bathing the physiological inside (dermal surface) of the skin. The maximum increase in sodium current recorded in the 15-min. period following the addition is taken as the response. Four-point balanced assays are performed. Synthetic oxytocin ('Syntocinon', Sandoz) is used as standard. Relative potencies are expressed in terms of units, one unit of natriferic activity being defined as the natriferic activity of one oxytocic unit of oxytocin. Calculations are based on the assumption of a linear regression of response on the logarithm of dose.

The results of natriferic assays on a bull-frog (*Rana catesbiana*) neurointermediate lobe extract, on synthetic arginine vasotocin, and on arginine vasopressin are shown in Table 1. There are wide variations of the values obtained for natriferic activity of arginine vasotocin and frog extract on different assays (the figures shown are geometric means of the results of five assays on each preparation). The variation appears primarily to be due to a 20-fold difference in the doses of oxytocin that must be used to obtain good responses in different frog skins. The sensitivity of the skins to frog extract or arginine vasotocin remains much more constant among different frogs. If one compares the natriferic values obtained when both frog extract and arginine vasotocin are assayed on the same skin there is a much more constant relationship between their natriferic activities. This may be taken as additional evidence in support of the contention that frog extract contains arginine vasotocin.

Activities of arginine vasopressin, oxytocin, bullfrog neurointermediate lobe extract and arginine vasotocin on other selected assays are also shown in Table 1. It appears that arginine vasotocin could, if present in the bull-frog neurointermediate lobe in a concentration of approximately 8 μgm./mgm. dry weight, account for the vasopressor, frog bladder, frog antidiuretic, and frog natriferic activities of the extract. The high oxytocic activity of the frog extract is believed to indicate that oxytocin is also present[10].

It appears probable that both natriferin and the frog water-balance principle are arginine vasotocin. It would not appear necessary, therefore, to ascribe the natriferic activity of frog and teleost pituitary extracts to a new hormonal principle[1] unless there is commanding evidence that such exists distinct from principles previously described.

Further work on the relationships between peptide structure and natriferic activity are planned. It is anticipated that this response will show a high degree of specificity as does the frog bladder response[8]. The presence of natriferic activity in neurohypophysial extracts from vertebrates other than those investigated by Maetz *et al.*[1] should also be investigated.

This investigation was supported by Grant No. A1940 from the National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, U.S. Public Health Service.

Effect of Reserpine on the Nucleotide and Catecholamine Content of the Denervated Adrenal Medulla of the Rat

RESERPINE causes a depletion of the catecholamines and adenosine triphosphate stored in the amine granules of the adrenal medulla[1-3]. This effect may, however, have been produced indirectly through the secretory nerves[3]. Such a stimulation of the medulla induced by insulin hypoglycaemia or morphine causes a concomitant release of amines and adenosine triphosphate[4,5]. The essential problem, however, is how reserpine causes amine depletion by direct action on the cells. As a preliminary attempt to elucidate this problem, the effect of reserpine on the nucleotide and amine content of the denervated rat medulla was studied.

The left adrenal medulla of twelve male rats (body-weight 350–400 gm.) was denervated by cutting the splanchnic nerves. This produces a total denervation[7]. After ten days the animals were divided into three equal groups. Reserpine (10 mgm./kgm. subcutaneously) was administered to each of the rats. The animals were killed 24 hr. after the injection and the adrenal medullæ were dissected, extracted and analysed for catecholamines and adenosine phosphates by means of high-voltage paper electrophoresis in the way described in a previous paper[6]. This method yields values for the adenosine phosphates which are somewhat higher than the real ones owing to the presence of other nucleotides[3]. Each extract contained the four left or right medullæ from the rats in each group. The rats were of the same weight and stock as those used in an experiment made at the same time. The normal animals in that work[6] were therefore taken as controls. Denervation of the medulla does not produce any certain changes of the nucleotide or amine content[6].

The results are presented in Table 1.

Table 1. µMOLES IN MEDULLÆ FROM 4 GLANDS

Normal glands		Catecholamines	ATP	ADP	AMP
	Mean	0·365	0·0845	0·0315	0·0096
Reserpine					
Denervated glands	I	0·280	0·0650	0·0235	0·0077
	II	0·190	0·0415	0·0225	0·0061
	III	0·230	0·0550	0·0215	0·0070
	Mean	0·235	0·0540	0·0225	0·0069
		−36%	−36%	−29%	−28%
Non-denervated glands	I	0·110	0·0245	0·0175	0·0063
	II	0·0570	0·0140	0·0115	0·0048
	III	0·0915	0·0200	0·0130	0·0052
	Mean	0·0860	0·0195	0·0140	0·0054
		−76%	−77%	−56%	−44%

Reserpine produced an amine depletion which was on an average 77 per cent in the normal glands and 36 per cent in the denervated ones. As previously found for normal medulla in fowl[1], rat[2], and sheep[3], disappearance of a corresponding amount of adenosine triphosphate occurred in both the normal and the denervated glands. The adenosine monophosphate and adenosine diphosphate content also decreased, but to a lesser extent.

Thus it seems that the release of amines from the adenosine triphosphate amine storage complex produced by reserpine through direct action on the cells is accompanied by a release and/or breakdown of an equivalent amount of adenosine triphosphate which, furthermore, does not lead to an accumulation of adenosine diphosphate or adenosine monophosphate. In this respect the direct reserpine action and the action of nervous secretory stimuli give a similar effect. This may mean that both reserpine and secretory stimuli act through the same mechanism (for example, activation of a release or inhibition of a storage mechanism). Considering the structure of the adenosine triphosphate amine storage complex[8], it seems probable, however, that an amine release—irrespective of the way in which it is brought about—must always be accompanied by a corresponding release (or breakdown) of adenosine triphosphate. The findings, therefore, only seem to imply that the amines released from the granules by reserpine do not accumulate to any appreciable extent in the cytoplasmic sap.

The investigation was aided by a grant from the Swedish Medical Research Council.

Effect of Three Compounds related to Diethylstilbœstrol on the Phagocytic Activity of the Reticulo-Endothelial System

IT has been reported previously that diethylstilbœstrol is a strong stimulant of the phagocytic activity of the reticulo-endothelial system[1]; that the minimum dose required to stimulate the phagocytes is about 100 times greater than that necessary to induce œstrus[2]; and that after treatment with 0·5 mgm. diethylstilbœstrol daily for six days the phagocytic activity returns to within normal control limits in about eight days[3].

The present communication is a report of the action on the phagocytic activity of the reticulo-endothelial system of three compounds related to diethylstilbœstrol.

Twenty-five male white mice (*T.O.* Swiss strain) of 20–25 gm. body-weight were used in these experiments. Five animals were used to test each compound, each animal receiving one subcutaneous dose of 0·5 mgm. of the compound in 0·05 ml. arachis oil daily for six days. On the eighth day after the commencement of the treatment the phagocytic activity was measured by the rate of disappearance of a known amount of specially prepared carbon from the circulating blood[4], the procedure used being that described in previous communications[1], and the total-body phagocytic activity or phagocytic index being denoted by the symbol *K*.

Ten of the animals were used as controls and were given 0·05 ml. arachis oil once daily for six days. The phagocytic activity was then measured on the eighth day by the carbon method referred to above. The arachis oil controls showed a phagocytic index or *K* value of 13 ± 2·4.

The results are shown in Table 1. The three compounds are active œstrogens, and it can be seen that all of them are strong stimulants of phagocytic activity. These results again suggest that the configuration of the molecule which confers œstrogenic activity is also essential for reticulo-endothelial stimulation. In addition, the results show that phagocytic stimulation

Table 1. Effect of Three Compounds related to Diethylstilboestrol on the Phagocytic Activity of the Reticulo-Endothelial System

Compound used	Phagocytic index (*K* value)	Weight of liver (gm.)	Weight of spleen (gm.)	Oestrogenic activity (R.U.)
Diethylstilboestrol monomethyl ether	85±31	1·79±0·11	0·13±0·01	0·0025 mgm.
Diethylstilboestrol dimethyl ether	88±19	1·66±0·17	0·15±0·04	0·02 mgm.
4-Hydroxy-α: β-diethyl dibenzyl	74±14	1·45±0·14	0·13±0·03	0·04 mgm
Arachis oil controls	13±2·4	1·14±0·17	0·11±0·03	

is accompanied by a corresponding enlargement of the liver and spleen. These are the principal reticulo-endothelial organs and it has been recorded previously that about 90 per cent of the carbon is removed from the blood by the liver, about 3 per cent by the spleen and the remainder by the phagocytes of the lymph nodes, connective tissue and bone marrow[5]. It was also found that the enlargement of liver and spleen is not due to water retention, but appears to be the result of hypertrophy of hepatic and splenic tissue.

In these investigations we gratefully acknowledge financial assistance from the Central Research Fund of the University of London and from the Medical Research Council.

Infra-red Examination of the Association of Cornea Proteins with Water

Water, the most abundant molecular constituent of the body, is the necessary polar solvent in which physiological and biochemical units associated with cellular biology occur. It forms hydrogen bonds with cellular components which contain polar structural groups such as the protein collagen[1] found in the cornea. Direct evidence for molecular perturbations that occur during change in water content in intact tissue has been lacking, although changes are believed to occur. The present work is concerned with the demonstration and interpretation of the changes that occur in the infra-red spectra of the ox cornea during dehydration and during attempts at re-hydration.

The tissue chosen for investigation was the ox cornea, which has a water content of 75–80 per cent with collagen making up about 70 per cent of the solids. Corneas were excised 1–3 hr. after the animals were slaughtered and then stored at 4° C. until ready for use. They were dehydrated by exposure to infra-red radiation during the runs, which usually lasted ½ hr. each, and they were allowed to dry between runs at room temperature in a desiccator. The Perkin-Elmer model 12 infra-red spectrometer with a sodium chloride prism was used for recording the spectra of the cornea, which was mounted in the slit position. The region of the spectra covered was 1·2–2·7μ.

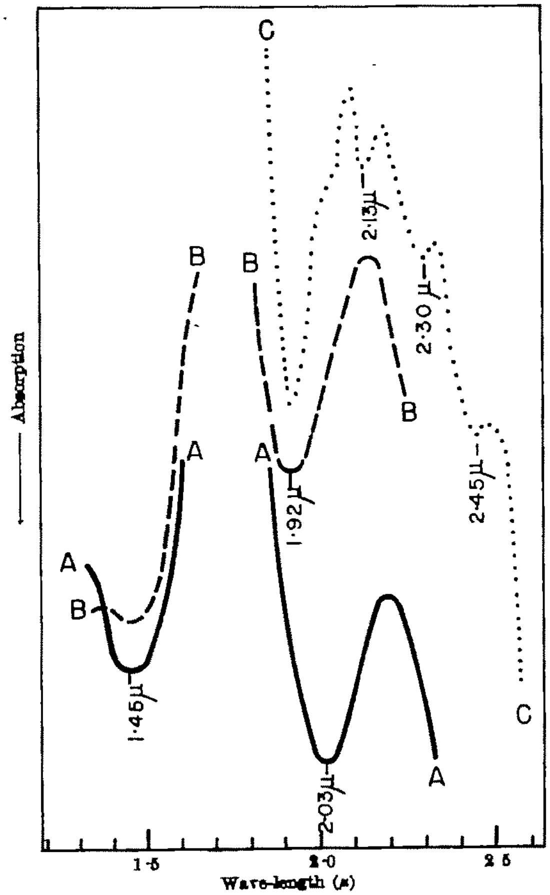

Fig. 1. Infra-red spectra of the ox cornea. —— *A*, fresh cornea; - - - *B*, 5-hr. specimen; · · · · *C*, 2-day specimen

Progressive stages in drying of the ox cornea are shown in Fig. 1. Curve *A* represents the spectral absorption curve immediately after excision. The spectra after 5 hr. and 2 days of drying are indicated by curves *B* and *C*, respectively. Immediately after excision, the maximum absorption bands were obtained at 1·45μ and 2·03μ. After dehydration for 5 hr., the wave-lengths of the absorption bands were 1·45 and 1·92μ, and after two days, they were 1·92, 2·13, 2·30 and 2·45μ. The absorption at 1·45μ in curves *A* and *B* of Fig. 1 is ascribed to water, which decreases between curves *A* and *B*. The absorption band in curve *A* at 2·03μ has been eliminated in the 5-hr. specimen (curve *B*) although water is known to be present since there is a residual absorption at 1·45μ. After 5 hr. the background absorption of the corneal protein is sufficiently intense in the 2μ region to obscure the absorption of the small amount of water present.

Attempts to rehydrate the corneas which had been dehydrated for 2 days were carried out by dampening with water and immersing in water for 30 min. and 2 days. In each case, there is an increase in absorption at 1·45μ and 1·92μ, which are approximately the absorption bands of water. The combined absorption curves of the 2-day-old specimen and that of water do not correspond to the original spectrum shown in Fig. 1, curve *A*. A number of determinations were made, and reproducibility was obtained for the initial and final runs.

The infra-red absorption curve obtained with dehydrated cornea to which water had been added does not correspond to the absorption spectrum of the original tissue. It is apparent that the withdrawal of water from the tissue leads to structural changes of the cornea, which are revealed by the infra-red absorption bands found in the dried tissue. The inability to re-establish the infra-red curve *A*, Fig. 1, by adding water to the dried tissue indicates that the polar groups which were associated with water in the fresh cornea are no longer available. The loss of water in the cornea apparently breaks the association between the protein and water molecules. Since the final dried cornea is hard and has the physical characteristics of a high molecular weight polymer, it is suggested that the active polar groups of the released protein may then become re-oriented among themselves to form higher molecular weight components.

We are grateful to the Air Reduction Research Laboratories, Murray Hill, New Jersey, for the use of their spectrometer and facilities in this investigation. This investigation was supported, in part, by a fellowship (S. B.), grant 2*G*125, from the U.S. Public Health Service.

Diuretic Activity of 2-Amino-4-metachloro-anilino-1,3,5,triazine (*R*-37)

A series of new derivatives of *s*-triazine synthesized in the Department of Chemotherapy, Haffkine Institute, Bombay, have been tested for their diuretic activity. Of the 12 compounds tested, 2-amino-4-meta-chloro-anilino-1,3,5,triazine (*R*-37), which is the metachloro analogue of amanozine, was found to be most promising. Diuretic activity was determined by a modified method of Lipschitz *et al.* (1943) developed in this laboratory[1].

Unanaesthetized rats received normal saline orally, 2·5 per cent of body-weight, followed by the drug under test. Urine was collected over a period of 5 hr. Dogs were anaesthetized, hydrated with normal saline, 2·5 per cent of body-weight, and the drug given intravenously. Urine was collected for the next 5 hr. by catheterizing both ureters, and urinary sodium, potassium and chloride were determined.

Results obtained with *R*-37 were compared with those obtained with urea and hydrochlorothiazide in rats, and with hydrochlorothiazide in dogs. The results of experiments with rats are given in Table 1, and those with dogs in Table 2.

Table 1. Results for Rats

Average of percentage excretion of initial load of water, sodium and chloride in groups of four animals. Potassium values represent average of total amount of potassium thrown out by each group

	Urea	Hydrochlorothiazide		*R*-37	
Dose (mgm./kgm.)	750	1·25	2·50	5 0	10·0
Groups	(14)	(8)	(8)	(8)	(8)
Sodium	30	80*	89	60*	154
Chloride	111	217	211	157	237
Water	61	71	64	58	122
Potassium	0 50	0 76†	0·90*	0·64	0·77*†

A '*t*' test for significance was carried out. Any two values not underscored by the same line or marked with same signs are significantly different (*P*, 0 01).

Table 2. Results for Dogs

Average of percentage increase over control values of urine volume and electrolyte excretion over intravenous administration of the drug; control observations are for 1 hr., while 'test' values are average of 5 hr. in each animal. Each figure is an average from three animals

Drug	Hydrochlorothiazide	Hydrochlorothiazide	*R*-37	*R*-37
Dose (mgm /kgm.)	2·5	5 0	5 0	10 0
Sodium	270	1,590*	100	1,130*
Potassium	315*	280*	55	360*
Chloride	390	1,185	265	835
Urine volume	470	225	230	1,110

A '*t*' test for significance was carried out. Any two values not underscored by the same line or marked with asterisks are significantly different (*P*, 0·01).

These results show that *R*-37 is a very powerful diuretic in animals and compares favourably with hydrochlorothiazide in the range of dosages of the two drugs employed by us. The drug has a good margin of safety in animals and is not toxic when used in diuretically active dosage given daily over a period of four weeks in animals. None of the dogs given *R*-37 in doses of either 5 mgm./kgm. (3 dogs) or 10 mgm./kgm. (3 dogs) showed any sign of hæmaturia or crystalluria.

A Suggested Effect on Levels of Catecholamine in Brain produced by Small Doses of Reserpine

In a recent communication, Sheppard and Zimmerman[1] criticized the results obtained by numerous other workers indicating that reserpine reduces the content of brain norepinephrine and serotonin. Their objections were based on the "toxicological doses" which had been used. However, they failed to mention that reserpine had also been reported to reduce levels of brain serotonin[2] and norepinephrine[3] in non-toxic doses as low as 0·1 mgm./kgm. and to deplete heart norepinephrine in doses as low as 5 μgm./kgm.[4]. Sheppard and Zimmerman's results showed that the administration of 0·1 mgm./kgm. of reserpine subcutaneously to female guinea pigs weighing 300 gm. elicited a rise of 74 per cent in brain norepinephrine in 20 min. and a rise in heart norepinephrine of 30 per cent in 20 min. and 45 per cent in 2 hr. No diminution in brain and heart norepinephrine was noted for 8 hr. In contrast, serotonin-levels in the brain fell by 50 per cent in 4 hr. They concluded that their results constituted the first demonstration of a rise in catecholamine content following the administration of reserpine.

Sheppard and Zimmerman measured norepinephrine fluorometrically by a procedure using a filter for isolating the activation and fluorescent light bands. Since filters have relatively wide spectral bands, the validity of their values is contingent on proof that the method for norepinephrine is specific. This is especially relevant in view of the presence of reserpine and its metabolites in the body. However, no evidence is offered for the specificity of the method.

We have repeated the experiments using a fluorescent spectrofluorometer which permits use of narrow spectral bands and methods of proved specificity for norepinephrine[5] and serotonin[6]. The administration of 0·1 mgm. of reserpine per kgm. subcutaneously to female guinea pigs weighing about 300 gm. at no time caused a rise in brain or heart norepinephrine. In 20 min., when Sheppard and Zimmerman had found a 74 per cent rise in brain norepinephrine, we found that serotonin and norepinephrine showed no change from normal, or perhaps a small decline. After 4 hr. the brain amine-levels were 60–70 per cent of normal (Table 1).

Table 1. GUINEA PIG BRAIN AND HEART AMINES AFTER ADMINISTRATION OF 0·1 MGM./KGM. OF RESERPINE SUBCUTANEOUSLY

		γ/gm.* ± *S.D.*	Percentage of normal
Brain serotonin	Control	0·28 ± 0·04	100
	Reserpine, 20 min.	0·28 ± 0·02	100
	Reserpine, 4 hr.	0·19 ± 0·04	68
Brain norepinephrine	Control	0·42 ± 0·04	100
	Reserpine, 20 min.	0·40 ± 0·02	95
	Reserpine, 4 hr.	0·25 ± 0·07	60
Heart norepinephrine	Control	2·71 ± 0·34	100
	Reserpine, 20 min.	2·46 ± 0·38	91
	Reserpine, 4 hr.	0·63 ± 0·30	23

* Each value represents the average from 6 animals.

Heart norepinephrine fell to 90 per cent of normal in 20 min. and was only 20 per cent of normal in 4 hr. (Table 1).

These results show that the fall in brain and heart amines after the administration of small doses of reserpine to female adult guinea pigs is qualitatively similar to that observed in other animal species when using larger doses of reserpine.

[6] Bogdanski, D. F., Pletscher, A., Brodie, B. B., and Udenfriend, S., *J. Pharmacol. Exp. Therap.*, 117, 82 (1956).

THE preceding communication contains data refuting the rise in catecholamines which we had observed 20 min. after the subcutaneous injection of reserpine (0·1 mgm./kgm.). In repeating the experiment in order to check the questioned specificity of the analytical method, we found that we were unable to reproduce our original findings. Instead, the brain catecholamine-levels expressed as percentage of controls were found to be 105, 100, 64, 26, 37 and 31 per cent after ½, 2, 4, 6, 8 and 72 hr. The shape of the curve was very much like that observed for serotonin and the 4-hr. values agreed with those reported by Orlans and Brodie. We are, at present, unable to detect the factors in the original experiments which gave us the values we reported, but we intend to pursue this matter further. In spite of this discrepancy, the serotonin values remain undisputed and the main conclusion remains valid, namely, that there exists no correlation between the levels of brain amines and the intensity of observable effects.

It is unfortunate that Orlans and Brodie, while correctly questioning the method of analysis for catecholamines, misinterpreted and mis-stated what was written in our original letter. Suffice it to say that our communication was not a criticism of the many skilled workers who had demonstrated the ability of reserpine to lower tissue amine-levels. Contained in it, however, was a criticism of the attempts by some workers to attribute the presumed central effects of large doses of reserpine (1–5 mgm./kgm.) to changes in the levels of brain serotonin or norepinephrine. The actions of reserpine described by Brodie *et al.*[1] as "loss of righting reflex, enhanced salivation and active closure of the eyelids" would be considered as undesirable toxic side-effects if found to occur clinically. To imply that such effects describe in equal fashion such terms as tranquillizing, sedative and central action of reserpine does little to clarify a terminology which is already too vague for scientific usage. It is important to define terms more clearly and to signify what responses one is trying to correlate with changes in tissue amine-levels. It remains to be determined which, if any, of the effects of reserpine may be attributed to changes in serotonin or norepinephrine-levels alone. Previous work with reserpine labelled with carbon-14 or tritium[2] had demonstrated that the alkaloid was present in the brain during the entire period of visible action of the drug, but that here too no correlation could be made between the intensity of response and drug-level. It is important to recognize that the application of other techniques as used in the study of behaviour may bring to light some actions of the drug which are not readily observed, and for which a correlation can be found with changes in brain amine and/or reserpine-levels. In our opinion, no experiment has been reported which conclusively eliminates reserpine, *per se*, as the active agent and establishes serotonin and/or norepinephrine in its place. It remains for future work to establish the true mechanism of action of reserpine and similar alkaloids.

HÆMATOLOGY

β-Globulin Polymorphism in Chimpanzees

INTRASPECIFIC variation in the electrophoretic mobility of serum iron-binding β-globulins ('transferrins') have been described in man[1,2], cattle[3–5], sheep[6,7], goats[8] and certain monkeys[4,9]. In all but monkeys these variations have been established as inherited.

We have recently examined the sera of 25 chimpanzees, *Pan satyrus*, and observed seven β-globulin phenotypes. Prior to our examination, these animals had been used for the assay of poliomyelitis vaccine. Fifteen were affected with spontaneously acquired tuberculosis. Serum was held 2–20 weeks at – 15° C. before use. Electrophoresis on borate-

	25

buffered hydrolysed starch gel was performed according to the technique described by Smithies[10]. Use of gel buffered with *tris*(hydroxymethyl)aminomethane[11] yielded less-satisfactory separation. The serum β-globulin of each animal was saturated *in vitro* with iron-59 (ferrous citrate)[3], a constant voltage of 4–5·5 V./cm. applied for 18–21 hr., and radioautographs obtained[3]. The serum of each animal was compared repeatedly with those of other animals. A diagram of observed transferrin types is shown in Fig. 1 and the frequency of these types in Table 1.

The inheritance of the observed phenotypes is unknown and likely to remain so because of the difficulty attendant on mating these animals in captivity. The designation of phenotypes as shown is thus entirely arbitrary. It seems possible, however, that the β-globulin phenotypes AA, CC and DD represent homozygous states. These phenotypes exhibit two to four bands the intensity of which is inversely related to mobility and in these respects are similar to cattle homozygous at the β-globulin locus[3]. Moreover, the *in vitro* mixture of equal parts of AA and CC sera results in an electrophoretic appearance indistinguishable from AC serum, suggesting that AC animals are hybrid at the β-globulin locus. Similarly, mixtures of phenotypes AA–DD and of phenotypes CC–DD are indistinguishable from AD and CD phenotypes, respectively. A BB phenotype was not observed although its existence might be predicted by the occurrence of BC sera.

The presence of faintly labelled zones of iron-binding β-globulins was overlooked in preliminary experiments, and thus there may be numerous additional zones, characteristic of each phenotype, which cannot be detected by the technique employed. The appearance of multiple β-globulin zones in homozygotes has been observed in a variety of animals[4–8] and may occur in man. Indeed, several human sera of Tf–CC type frequently exhibited, as shown in Fig. 1, a faintly labelled band lying midway between the position of C and D$_1$ in man. The serum of one CD$_1$ individual, a Negro woman with systemic lupus erythematosus, was repeatedly examined and exhibited the faintly labelled slow-moving band indicated in Fig. 1. Such bands may, of course, be artefactual in nature.

One explanation for a multiplicity of 'transferrin' zones may lie in the polymerization of some parent protein unit. Such a hypothesis appears quite likely in the case of human haptoglobins[12].

It was noted in passing that the haptoglobin of each chimpanzee, when fully saturated with human hæmoglobin A, appeared as a single band lying in approximately the same position as human haptoglobin *Hp* 1–1. Some animals with gross anatomical evidence of pulmonary tuberculosis had haptoglobin hæmoglobin binding capacities in excess of 300 mgm. per cent, while others with the same disease had less than 30 mgm. per cent[13].

We wish to thank Dr. David Bodian for providing the chimpanzees studied and Dr. Neal Nathanson for his assistance.

This work was supported in part by United States Public Health Service Grant No. B2053 from the National Institute of Neurological Disease and Blindness.

Effect of Ribonuclease on Erythrocyte Antigens

RESULTS reported earlier from this laboratory suggest that the Rh and Lutheran human blood-group antigens owe at least some portion of their specificity to ribonucleic acid derivatives[1,2]. These observations were later confirmed by Allen (personal communication). Boyd, McMaster and Waszczenko-Zacharczenko[3] reported that they could not confirm the results cited above. However, more recently Boyd (personal communication) has observed an inhibitory effect reported earlier for these ribonucleic acid derivatives. This hypothesis has been further tested by treating erythrocytes with the enzyme ribonuclease. (Two samples from Worthington and one from Nutritional Biochemicals were used.) If, indeed, any antigenic specificity is due to ribonucleic acid derivatives, then treatment with this enzyme should remove these, at least partially, from the cells, and thus lower the agglutinability of these cells with the antibodies specific for the affected antigens. On the other hand, those antigens which are presumed not to involve ribonucleic acid derivatives should be unaffected by this treatment.

Table 1

Antibody	Sample No.	Titration scores Treated with ribonuclease	Titration scores Untreated (saline control)	Enzyme concentration (mgm./ml.)	Time (hr.)
Anti-A	1	85	85	2	2
	2	91	91	2	4
	3	93	93	2	4
	4	88	88	2	11
Anti-B		88	88	2	4
Anti-M	1	47	48	2	2
	2	60	59	2	4
Anti-N		53	53	4	4
Anti-P		12	12	2	4
Anti-I	1	36	36	2	2
	2	35	33	2	2
Anti-Lu^a		16	28	4	4
Anti-Lu^b		12	30	4	4
Anti-D	1	41	56	2	2
	2	30	56	2	2
	3	45	60	4	4
	4	50	71	2	11
Anti-C	1	52	72	2	2
	2	51	62	2	11
	3	52	64	4	4
	4	27	48	2	2
	5	21	48	2	2
Anti-E		29	47	2	2
Anti-c		13	25	2	2
Anti-e	1	43	59	2	2
	2	38	50	2	4

Samples of packed cells were incubated for varying times, as is shown in Table 1, with the enzyme ribonuclease. The enzyme concentration was 2 mgm./ml. or 4 mgm./ml., and ten volumes were used with a single volume of cells. Identical controls were set up using saline instead of ribonuclease. After incubation with either ribonuclease or saline, the cells were washed, and matched cell suspensions prepared. These were titrated with the various antisera shown in Table 1, and scored on the Race scale[4]. Only saline agglutinins were used.

With anti-A, -B, -M, -N, -P and -I, as can be seen in Table 1, there is no appreciable difference in titration scores between the cells treated with ribonuclease and the controls incubated in saline. However, with the anti-Rh and the anti-Lutheran antibodies, the agglutinability of the treated cells is apparently much less than the untreated controls. While not attempting here to evaluate optimum time or enzyme concentration for the reaction, it seems clear that under all sets of conditions tested, the treated cells have lost part of their Rh and Lutheran specificities at the same time as the other antigens tested for were unaffected. Since the activity of the enzyme, ribonuclease, is highly specific in that it acts only on polyribonucleic acids, it seems reasonable to conclude that the loss of ribonucleic acid components from the cell caused the lowering of agglutinability of the cells. This, added to the evidence of inhibition of agglutination cited above, would suggest still more strongly that there are one or more ribonucleotide components of the Rh and Lutheran antigens.

BIOLOGY

A Bleached Variant of *Euglena gracilis* showing a Doubling of the Content of Deoxyribonucleic Acid

WHEN certain strains of the green flagellate *Euglena gracilis* are grown at 34–35°, cultures devoid of chloroplasts are obtained[1]. These cells, which we term bleached, resemble the normal organisms cultivated in the dark (designated colourless), but they have lost a hereditary character necessary for the formation of the plastids[2]. In the course of a study of the chemical changes attending the loss of the photosynthetic apparatus in *Euglena*, a bleached culture ('Bleached II') derived from the normal strain *z* by thermal treatment, which had been carried through frequent liquid transfers for about three years, was found to contain twice the amount of deoxyribonucleic acid that is present in the original green or colourless cells. A comparison of the properties of this bleached variant with those of colourless cells showed the first to contain also more ribonucleic acid and protein and to have a slower rate of growth. Although the nuclei of these two cell types, when treated by the Feulgen method, appeared of equal size, those of the bleached organisms were coloured more intensely.

In an attempt to study this phenomenon in more detail, we produced clones of bleached cells by cultivation either at 34° or in the presence of streptomycin (10 mgm./ml.)[3]. These newly produced bleached organisms ('Bleached I') contained, to our surprise, an amount of deoxyribonucleic acid identical with that of the normal cells; nor did the further cultivation of these cells at 34° for several weeks with frequent transfers bring about an alteration in the normal nucleic acid content. Clones obtained from spontaneously occurring bleached cells also were found to contain the normal quantity. Table 1 records the contents of nucleic acid and protein found in the colourless cells and the two types of bleached organisms. The quantity of deoxyribonucleic acid present in green cells grown in the light is the same as that found in the colourless organisms.

It would appear that the doubling of the content of deoxyribonucleic acid in the bleached strain of type II constitutes a newly acquired and stable hereditary characteristic that may be described tentatively as an instance of experimentally induced polyploidy or polyteny. A change in the timing of the duplication of deoxyribonucleic acid during the interphase could, however, also simulate an alteration

Table 1. Properties of Colourless and Bleached Cells of *Euglena gracilis*, Strain z*

Type of cells	Deoxyribonucleic acid (µmol. per 10^7 cells)	σ	Ribonucleic acid (µmol. per 10^7 cells)	Protein (mgm. per 10^7 cells)	Generation time (hr.)
Colourless	0·09	0·02	0·60	2·1	7·3
Bleached I	0·11	0·02	0·67	2·2	8·0
Bleached II	0·20	0·04	0·80	3·3	8·8

* The cells were grown in the medium described previously (ref. 4). The chemical analyses were performed on large cell samples taken from cultures in the late logarithmic phase. The nucleic acids were determined by a modification, to be described later, of the Ogur–Rosen method (ref. 5), protein was estimated by means of the biuret procedure (ref. 6). The standard deviation is given as σ. The generation time was measured in cultures in the early logarithmic phase.

of the cellular content of this substance; and in the absence of a detailed cytochemical study this possibility cannot be excluded entirely. Our observations on the bleached cultures of type I demonstrate that the increase in deoxyribonucleic acid is not an obligatory consequence of the loss of chloroplasts in *Euglena*. That this augmentation is connected in some manner with the bleaching treatment is indicated by our findings with the bleached cells of type II and also by a recent report[7] describing a 50 per cent increase over the normal in the deoxyribonucleic acid contents of two bleached strains of *Euglena gracilis*. The reason for this phenomenon is obscure. It could, perhaps, be considered as significant that all bleached strains exhibiting the increase in deoxyribonucleic acid had been carried for several years before being analysed. Though the nature of the environmental stimulus giving rise to this alteration cannot be defined, a selection effect may be ruled out, since the cells characterized by a doubling of deoxyribonucleic acid, having a longer generation time, could scarcely have competed successfully, in the medium employed, with the organisms carrying the normal complement.

We are indebted to Dr. Arline D. Deitch for the examination of the preparations treated by the Feulgen procedure. This work was supported by research grants from the American Cancer Society and the National Science Foundation.

Plastids of the *Avena* Coleoptile

Phototropic curvature of the *Avena* coleoptile may, for reasons which have been summarized elsewhere[1], be mediated through the plastids. Geotropic curvature may have a similar basis, for it has long been thought[2,3] that the geotropic responses of both shoots and roots are mediated by special starch grains or 'statoliths', and these in fact are plastids in which relatively large amounts of starch have been deposited. It is thus worth considering that the many similarities between these two types of tropism may have an anatomical basis. For this reason a closer study has been made of the plastids of the etiolated *Avena* coleoptile. The observations have been made with the light and phase microscope, utilizing either fresh material vitally stained with neotetrazolium chloride, or microtome sections fixed in chrome-acetic-formalin and embedded and sectioned in 'Carbowax'. (We wish to thank Prof. R. H. Wetmore and Dr. J. Riopel for assistance and for putting at our disposal the newly developed 'Carbowax' method.) Principal attention has been directed to the most apical part of the coleoptile.

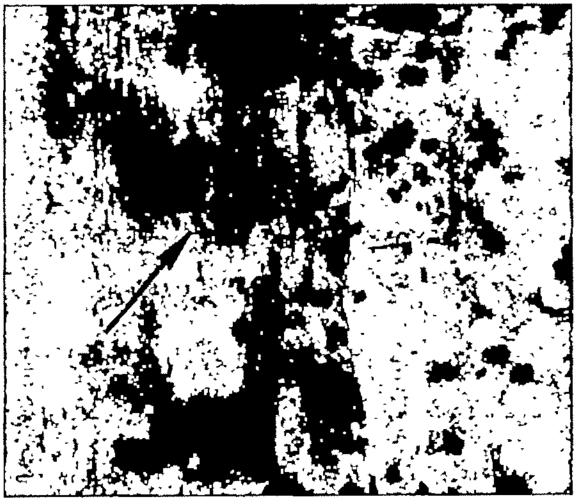

Fig. 1. From lower part of the coleoptile. Basal arrangement of the statoliths in two rows of cells only. (× 733)

Plastids are seen in all cell-layers except the inner and outer epidermis, which appear not to contain them. Our observations indicate that they are of two types. The first do not react with neotetrazolium, when fully developed, and contain mainly starch, which stains red-brown with iodine. These occur in abundance at the very tip of the coleoptile and also in

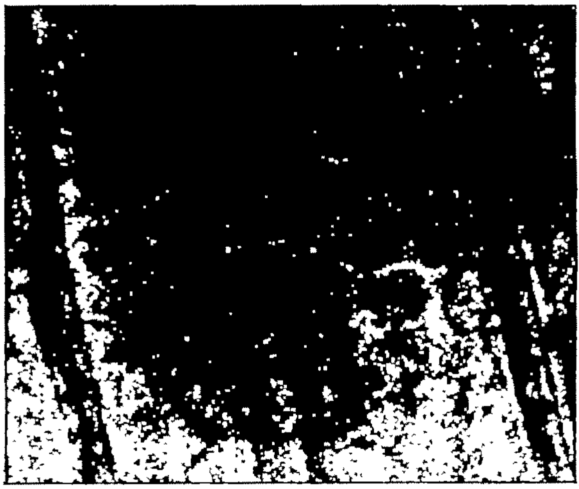

Fig. 2. Prolamellar body of the etiolated plastid after treatment with neotetrazolium and succinate showing the localization of dehydrogenase activity. (× 1,755)

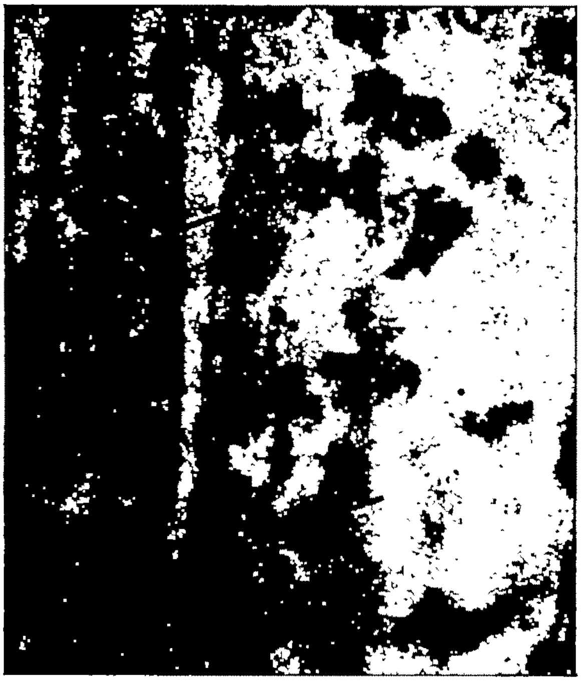

Fig. 3. Lobate outgrowth of the prolamellar body in cells similar to Fig. 2 after 1 hr. exposure to red light. Treatment as in Fig. 2. (× 1,755)

the subepidermal and middle layers around the fibro-vascular bundles. Thus these plastids are principally located in an arch rising outside and around the bundles; in the lower part of the coleoptile the sides of the arch have a thickness of two cells (Fig. 1), while the top has many layers. In plants which have been held vertical, sectioned under red light, mounted in iodine solution, and examined immediately, these bodies are found congregated at the basal end of the cells (Fig. 1). In plants which had been illuminated beforehand the basal arrangement of these plastids is not evident. Plastids of this type are without doubt identical with the statoliths described by von Guttenberg[4]; Yocum[5] has shown that these bodies roll down to rest on the lateral wall shortly after the plant has been placed horizontal. In the cells on the two sides remote from the bundles, these plastids occur sporadically and do not take up the characteristic basal position.

The second type occurs in highest concentration near the base of the tip portion, close to the apical termination of the vascular bundles; this point lies some 200μ below the extreme tip and 50μ above the uppermost end of the cavity. These plastids vary in size from 1 to 4μ and often contain a granule, 1–1·5μ in diameter, which stains strongly with neotetrazolium in presence of $M/20$ succinate or malate (Fig. 2). There is reason to identify this granule with the prolamellar body of etiolated plastids. Other cells contain these plastids in smaller numbers.

When the plants are illuminated with red light (wave-length 600 mμ and above) for 30 min. or more, the granule is found to have expanded into an X or lobate form (Fig. 3). This observation parallels that of the outgrowth of the 'crystalline' body into the lamellated structure of the typical chloroplast, which has been several times figured by the electron microscopists[6-9] and appears to establish this type of plastid as a pro-chloroplast. It is of interest, however, that the 'prolamellar body' is made evident by its dehydrogenase activity rather than by any special optical property. It is of still further interest that pre-exposure of the coleoptile to red light markedly modifies its subsequent phototropic sensitivity to white light[10]; such parallelism helps to support the concept of a close and causal relation between the proplastids and phototropic sensitivity.

Anastomoses in the Phycomycetes

IT is commonly assumed, either explicitly[1] or implicitly[2-4], that the vegetative mycelium of the Phycomycetes is incapable of vegetatively anastomosing and that this whole class of fungi is thereby precluded from developing complex fruiting-bodies and from undergoing variation by those means, such as heterokaryosis, which largely depend on the vegetative transfer of nuclei from the cells of one thallus to another.

Such an assumption is certainly confirmed by an examination of most cultures, but one of us (D. M. G.) has occasionally noticed the presence of anastomoses in a number of mycelia which, by their completely aseptate nature, are certainly those of Phycomycetes. Such cultures, isolated from soil in Britain and Australia, have usually been sterile, although one produced a few *Mortierella* sporangia, and the growth characteristics of the others lead us to believe that they belong to the same genus. Some are characterized by a normal system of scalariform anastomoses; but recently an isolate has come to hand in which the anastomoses are massive and comparatively crude, consisting of roughly conical projections, fused at their apices, from two adjacent hyphæ. In both types, extensive protoplasmic flow through mature anastomoses and their supporting hyphæ has been observed. A survey of other genera in the Phycomycetes, especially in the Aplanatae, and of other species of *Mortierella*, has failed to demonstrate the presence of further anastomoses, nor are they mentioned in Turner's[5] detailed description of *M. globulifera*.

This demonstration of the occurrence of anastomoses in at least one phycomycetous genus disrupts one of the "boundary conditions describing the Phycomycetes"[1]. It is also of interest in the fields of fungal variation and plant pathology, for it does not seem inconceivable that anastomoses could occur in other species under certain conditions, with the consequent possibility of heterokaryosis, etc. Such an occurrence would be particularly difficult to detect in the obligate pathogens of the Peronosporales.

Occurrence and Function of the Provisional Embryonic Cuticle of a Lepidopteran

The provisional embryonic cuticle has been noticed in several groups of insects such as Aphidae, Orthoptera, Hemiptera, Neuroptera and some types of Coleoptera[1]. It was, therefore, of interest to note the presence of the provisional embryonic cuticle in the hitherto unreported group of Lepidoptera.

Various roles have been ascribed to the provisional embryonic cuticle. It has been described as acting as an "egg burster" by Wigglesworth and Sikes[2] and others. It is also regarded by some as affording protection to newly emerged nymphs of grasshoppers when the young ones crawl from the buried egg-pods to the surface.

I believe[3] that the moulting of the provisional embryonic cuticle in *Locustana pardalina*, *Tenebrio molitor* and *Dysdercus cingulatus* (unpublished work) is due to developmental causes. Moulting is induced in order to synchronize the rate of deposition of cuticle with the development of muscle ends, so that a proper integration between the muscle and the cuticular exoskeleton can take place. The provisional cuticle is precociously formed, in the sense that it is formed at a time when the muscles are not in a position to become attached to it by means of tonofibrils. While the other functional interpretations are certainly valid, there is reason for believing that they are secondary adaptations.

In *Attacus ricini* (Lepidoptera), the provisional embryonic cuticle was first detected histologically and also with the help of histochemical methods at about eighty hours before emergence. The second or definitive cuticle was secreted soon after the sloughing of the provisional embryonic cuticle. A thorough examination of the development of skeletal muscles showed that the muscle bands were in an early state of development, mostly in the form of myoblasts at the time of secretion of the provisional embryonic cuticle. The muscles were well formed at the time of the secretion of the definitive cuticle, and it is to this cuticle that the muscles could become properly attached (Fig. 1).

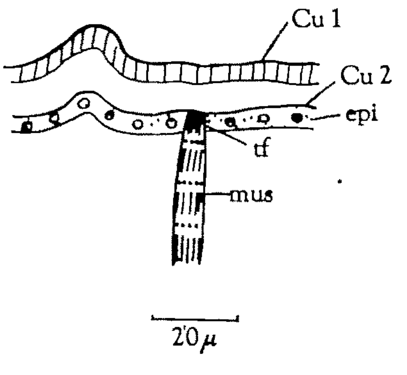

Fig. 1. epi., epidermis; Cu 1, provisional embryonic cuticle; Cu 2, definitive cuticle; mus., striated muscle fibre; tf., tonofibrils

The present investigation on *Attacus ricini*, therefore, confirms the conclusions reached for *Locustana*, *Tenebrio* and *Dysdercus*.

It is hoped to publish details elsewhere with Mr. Sahani of this Department. Mr. Barkat, of Government Farm, Ranchi, kindly made the eggs available for this work.

Incorporation of Acetate into Protein by Obligately Parasitic and Saprophytic Fungi

The germ tubes of obligate parasites such as the rust fungi and powdery mildews fail to grow in the absence of host plants. This may be caused by metabolic blocks, the general location of which should be revealed by studies on the distribution of radioactive tracer among the various broad classes of metabolites. To determine if this would be a feasible approach to the problem of obligate parasitism, the assimilation of radiocarbon by uredospores of a rust fungus (*Uromyces phaseoli* (Pers.) Wint.) and conidia of a saprophyte (*Aspergillus niger* van Tiegh) was studied to see if any important differences in metabolism occurred between them. The preliminary experiments reported here were made with non-germinated spores, so the metabolism studied was essentially catabolic in character.

Spores of the two fungi were compared with respect to their capacities to incorporate the methyl carbon of $^{14}CH_3COONa$ into sugars, amino-acids, Krebs-cycle acids, proteins, nucleic acids, and lipids. Spores of each species were incubated with 10 μc. of $^{14}CH_3COONa$ for various time-periods and then killed with boiling 80 per cent ethanol. Techniques for the separation and analysis of the various components have been described elsewhere[1].

The results are given in Table 1 and Fig. 1. The principal differences between the two species occurred in the total activity incorporated and the patterns of

Table 1. Distribution of Carbon-14 in Amino-acids from Fungous Spores incubated 10 hr. with 10μc. $^{14}CH_3COONa$

Amino-acid	Free amino-acids		Protein amino-acids	
	U. phaseoli	*A. niger*	*U. phaseoli*	*A. niger*

Tyrosine	0	0	0	0
Valine	13	0	0	1
Total c.p.m. per mgm. N	72,000	265,000	26,500	221,000

Results are given as percentage of total c.p.m. per mgm. protein nitrogen. Detectable label was not found in cysteine, methionine, phenylalanine, histidine or glycine. About 200 c.p.m. were required for detection by the methods employed.

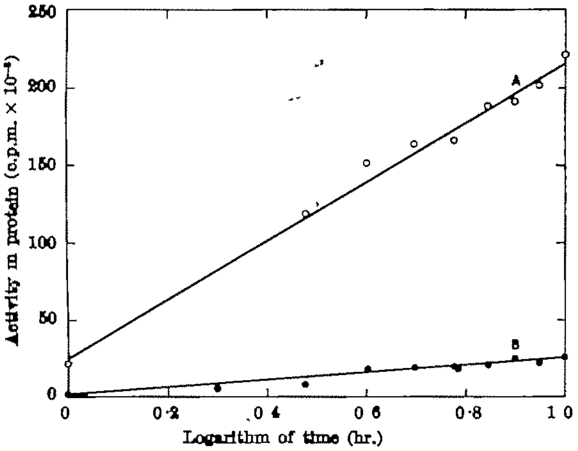

Fig. 1. Rate of incorporation of carbon-14 from $^{14}CH_3COONa$ into the protein fractions of: *A*, conidia of *A. niger*; *B*, uredospores of *U. phaseoli*

labelling of the protein fractions. Conidia of *A. niger* incorporated about 2,000,000 c.p.m. per mgm. of protein nitrogen during a 10-hr. exposure period, or about 10 times the amount of label assimilated by uredospores of the bean rust fungus. Most of the amino-acids in the protein fraction of *A. niger* became labelled in 10 hr. except for cysteine, methionine, phenylalanine, histidine, and glycine. Labelling in the free amino-acid fraction of this fungus was much more restricted, being confined to the leucines, glutamic acid, and glutamine. The specific activities of the amino-acids in the protein fraction of uredospores were much lower, and label was not found in valine or the leucines in addition to the acids not labelled by *A. niger*. A larger number of free amino-acids were labelled by bean rust spores than by *A. niger*; but specific activities were much lower than those isolated from conidia, reflecting low incorporation of exogenous substrate by uredospores.

Thus the rust spores were able to synthesize the same amino-acids from acetate as conidia of *A. niger*, but the over-all incorporation of substrate was lower. In addition, amino-acids were synthesized much more rapidly by conidia than by uredospores. For example, labelled valine was found in conidia in 2 hr., but did not appear in uredospores until 5–10 hr.

At least two amino-acids labelled by uredospores, valine, and leucine(s) were not incorporated into protein. This may have arisen from the fact that the capacity of uredospores for incorporating label into protein fell rapidly with time. When radioactivity in the protein fractions was plotted against the logarithm of time, linear relationships were obtained for both fungus species (Fig. 1). The regression equation relating carbon-14 assimilated, in terms of c.p.m. × 10^{-3} per mgm. protein nitrogen (L), to time of incubation in hr. (t) was found to be:

$$L = 26 \log_{10} t - 0{\cdot}8$$

for the bean rust fungus, with a correlation coefficient of $+0{\cdot}975$.

For *A. niger* the regression equation was found to be:

$$L = 220 \log_{10} t + 3{\cdot}7$$

with a correlation coefficient of $+0{\cdot}995$. Thus it is seen that the regression coefficient relating activity in the protein fraction to the logarithm of incubation time was 8·6 times higher for *A. niger* than for *U. phaseoli*, suggesting that failure of the latter species to incorporate valine and the leucines may arise from a loss of the mechanism for this incorporation.

Therefore, amino-acids which require long periods of time for synthesis may not become labelled soon enough for activity to be incorporated into protein. At least 5 hr. must elapse before the label can be detected in the free leucines isolated from rust spores, by which time incorporation of label into protein has fallen to a small fraction of the initial rate. The results indicate that the metabolism of resting uredospores is characterized by a rapid loss of ability to incorporate substrates into protein, coupled with low utilization of exogenous substrate, and a very slow rate of synthesis of some important amino-acids.

MICROBIOLOGY

Adaptive Chain in the Conversion of Antimetabolites into Metabolites

THE adaptation of micro-organisms[1] and insects[2] to antimetabolites used in the control of the latter is an important contemporary problem. It has been conjectured that a possible mechanism for such adaptation might be: formation of new metabolic pathways, creation of inhibitors or enzymes neutralizing antimetabolites, or modification of the permeability of structures sensitive towards antimetabolites[3,4]. These mechanisms, in so far as they concern penicillin, would involve an induced biosynthesis of penicillinase which suppresses the antimetabolic activity of penicillin, an autotrophic biosynthesis of amino-acids the assimilation of which by the milieu is inhibited by penicillin[5], or a modification of bacterial surface structure[6]. All or any of these mechanisms might make the antimetabolite innocuous to the living cell.

The present investigation was undertaken to direct attention to some accessory mechanisms subsequent to the adaptation of micro-organisms to antimetabolites.

We established in 1956 (ref. 7) that, for penicillin-resistant *Staphylococci* (not penicillin-dependent), benzylpenicillin serves as a growth factor, replacing thiamine in a nutrient medium containing nicotinic acid[8] but deficient in thiamine. We found that this effect occurs solely with benzylpenicillin and its derivatives, which lack antibacterial activity, benzylpenicilloinic and benzylpenillic acids; it does not occur with other derivatives of penicillin and similar antibiotics[9]. The growth effect observed for concentrations of 10^{-10}–10^{-11} *M* is of the same order as that due to thiamine. A similar growth effect due to vitamins was observed only in the case of thiamine pyrophosphate, thiamine and biotin.

These results should show whether, as a result of adaptation to benzylpenicillin, there appears a novel growth factor, or whether it is converted to thiamine

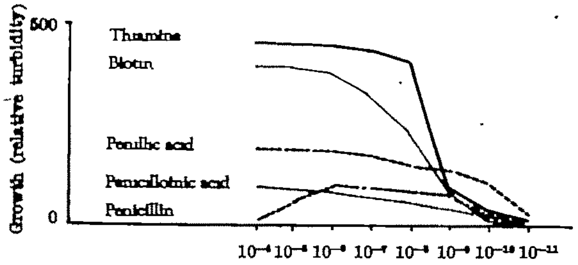

Fig. 1. Growth of *Staph. aureus* 671, cultivated during 48 hr. at 37° C. on a nutrient medium containing $1 \cdot 6 \times 10^{-8}$ *M* nicotinic acid (ref. 8), as well as the substances named at concentrations given on the abscissa

or biotin. In order to clarify the mechanism involved, the effect of the substances named in Fig. 1 on various metabolic processes has been studied.

With *Staphylococci* deficient in thiamine and resistant to penicillin[10], it has been established that thiamine, penicillin and biotin all activate respiration in a similar degree, approximately 60 per cent, on a glucose substrate. Respiration in the case of pyruvate and lactate as substrates is activated particularly by thiamine and thiamine-pyrophosphate, and rather less—though to a practically similar degree—by biotin and benzylpenicillin (also benzylpenicilloinic and benzylpenillic acids); see Table 1.

Table 1. RESPIRATION OF *Staph. aureus* WITH 0·025 *M* PYRUVATE OR LACTATE AS SUBSTRATE AND CONCENTRATION OF SUBSTANCES TESTED $2 \cdot 5 \times 10^{-4}$ *M*

Penicillin stimulates the respiration of penicillin-resistant *Staphylococci*. Thus, if our penicillin-resistant strain (*Staph. aureus* 315) is cultivated on a nutrient medium containing benzylpenicillin in a concentration equal to that showing resistance, but not with the object of modifying resistance, the activating effect of the penicillin on respiration is increased about threefold as compared to the initial stage. The stimulating effect of penicillin on respiration is not shown immediately on the introduction of penicillin, but after some 45 min.; whereas with thiamine, thiamine-pyrophosphate and biotin, activation of respiration is shown immediately on their introduction.

These tests suggest that penicillin is an adaptively formative growth factor, probably different from thiamine and related to or identical with biotin.

In order to study the interaction between penicillin and biotin as metabolites for penicillin-resistant *Staphylococci*, we have tested the introduction of the carbon from bicarbonate into the protein mass of penicillin-resistant *Staphylococci* (Table 2).

Conditions were as follows: 2 hr. incubation at 40° C. in a medium containing, in ml.: 4 mgm. casein hydrolysate-vitamin free; 5 mgm. dipotassium hydrogen phosphate, 4 mgm. glucose, 0·8 μc. sodium bicarbonate-^{14}C, nicotinic acid, 10^{-8} *M*, substances under test at 10^{-8} *M* concentration, micro-organisms 3·4–4·6 mgm. nitrogen and *p*H 7·4. The results are given in impulses/min. for 0·6 mgm. protein nitrogen, while the values in brackets indicate the percentage relating to the control less growth-factor. The tests were carried out with the penicillin-sensitive strain 209, its resistant variant 209*P*, obtained by culture on nutrient media containing penicillin and the penicillin-resistant strain 671.

Likewise, we have measured the rate of introduction of methionine-^{35}S. Under similar conditions, the increased rate of introduction of amino-acid under the influence of penicillin was found not to exceed 10 per cent.

The results obtained indicate that penicillin, similar to biotin, activates the fixation of carbon dioxide (Wood and Werkman reaction), forming products presumably converted into amino-acids, utilized for protein synthesis. It is difficult to appreciate whether the penicillin is adaptively converted into biotin, or whether it acts as a new, adaptively formed metabolite synergistic to biotin. With resistant strains, the rate of introduction of carbon dioxide into the protein mass is many times greater than in the sensitive strains. This is probably the manifestation of the autotrophic formation established by Gale and Rodwell[9] of the amino-acids necessary for protein synthesis in the case of penicillin-resistant *Staphylococci*. Evidently, penicillin as a metabolite for penicillin-resistant *Staphylococci* is introduced precisely into those links of the metabolism which develop with the establishment of resistance.

Our results show that, in the case of penicillin-resistant *Staphylococci*, both penicillin and its product for rendering penicillinase innocuous—penicilloinic acid—serve as metabolites. Similar cases have been described with other metabolites. Thus, chloramphenicol is made innocuous by bacteria, being transformed into *p*-aminobenzoic acid[11]. The antimetabolite of riboflavin-6-chloro-7-methyl-9-(1′-D-ribityl)-*iso*alloxazin may be adaptively utilized by *Lactobacillus casei* as a metabolite[12].

These manifestations lead us to believe that they are an expression of a more general biological occurrence of an adaptive conversion of antimetabolites to metabolites. The chain of complete adaptation as regards some metabolites may be rendered schematically thus:

antimetabolite → indifferent product → metabolite

The adaptation of *Staphylococci* to penicillin observed by us embraces this entire, complete adaptive process. Further, the penicillin antimetabolite converted into a metabolite is launched into a diametrically contrary direction, assisting the organ-

Table 2. INTRODUCTION OF THE CARBON FROM BICARBONATE INTO THE PROTEIN OF *Staphylococci* UNDER THE INFLUENCE OF VARIOUS FACTORS

Strain	Resistance (U./ml.)	Control	Biotin	Penicillin	Thiamine
Staph. aureus 209	0·03	218 (100)	288 (132)	147 (68)	257 (118)
Staph. aureus 209*P*	5,000	297 (100)	365 (123)	344 (116)	293 (99)
Staph. aureus 671	1,000	839 (100)	1,128 (134)	1,006 (120)	727 (87)

isation of autotrophic mechanisms which lead to the by-passing of metabolic links affected by penicillin.

A Vacuolar System in Cells of *Agrobacterium tumefaciens* as shown by Electron Microscopy of Ultra-thin Sections

ELECTRON microscope studies of ultra-thin sections of the cells of several species of bacteria made by different workers have shown a regular structural pattern which can be summarized as follows: a definite cell wall, a cytoplasmic membrane (Chapman[1]), a granular cytoplasm with one or more round, dense inclusions called chondrioids (Kellenberger *et al.*[2]), and a more or less central core which is irregular in shape and low in density to the electron beam. Comparative studies of stained preparations with the light microscope have led various workers to associate this core with nuclear structures, and it has been called vesicular nucleus, kernvacuole, kernäquivalent, nucleoide, nuclear sites, and nuclear apparatus. Reticulated structures within this core have been considered to be nuclear material, deoxyribonucleic acid or even chromosomes.

Cells of *Agrobacterium tumefaciens* grown on nutrient agar slants for 48 hr. were fixed in potassium permanganate, incorporated into agar blocks, and embedded in methacrylate. Ultra-thin sections were cut with a diamond knife and photographed in the R.C.A. *EMU3B* electron microscope. In the micrographs we have obtained, we have observed some of the structures described above (Fig. 1). However, after removal of the methacrylate with benzene, followed by shadow-casting with palladium, the central core of low electron density is observed as a vacuole crossed by a few strands and with some dense granules protruding from the cytoplasm into it (Fig. 2). Structures that could represent a vacuolar membrane have not been observed.

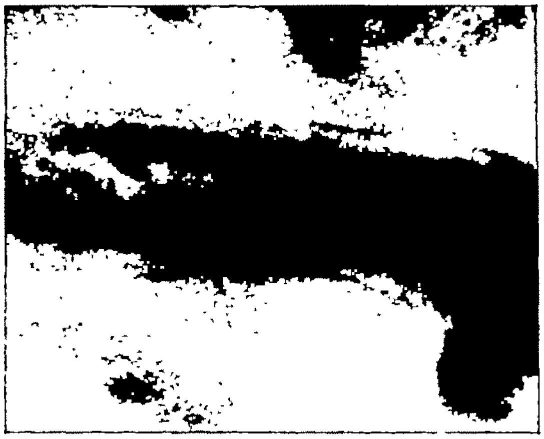

Fig. 1. Cells fixed in 5 per cent potassium permanganate in veronal–acetate buffer, pH 7·5, embedded in methacrylate. (× 42,000)

The presence of a vacuolar system had been observed in other bacteria: Houwink[3] showed in *Halobacterium halobium* a complex vacuolar system not related with the nucleus; and Knaysi[4] working with *Mycobacterium thamnopheos* stated that "the destructive effect of acid hydrolysis . . . is attributed to the presence of vacuoles in the cells of this organism". The empty vacuoles revealed in our work do not seem to correspond to regions with appreciable concentration of deoxyribonucleic acid. Also the absence of a definite membrane limiting these vacuoles, as Birch-Andersen and Maaløe[5] pointed out, gives evidence that the vacuoles with their contents are structures not related with distinct nuclei which are generally separated from the rest of the cell, but probably correspond to the vacuolar systems found in many other vegetative cells.

The work of Knaysi[6] on *Bacillus cereus*, in which he observed the division and fusion of dense granules, indicates that the nuclear sites correspond to areas denser than the cytoplasm, and that some of the so-called cytoplasmic inclusions could be the real sites of the nuclei. Preusser[7], studying ultra-thin sections of *Escherichia coli*, stated that the zones of low electron density within the bacterial cells are products of cellular metabolism and are not comparable with the nuclei of higher organisms. On the other hand, the correspondence observed between the light areas in electron micrographs of ultra-thin sections and the stained nuclear material observed in the light microscope is probably due to the fact that the whole thickness of the bacterial cell is in focus in the light

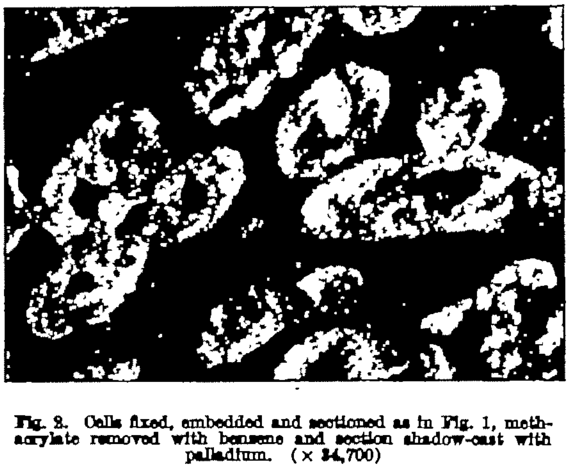

Fig. 2. Cells fixed, embedded and sectioned as in Fig. 1, methacrylate removed with benzene and section shadow-cast with palladium. (× 34,700)

microscope, having been flattened by fixation or drying. It is, therefore, impossible to be certain whether the stained matter which appears within the lighter areas is actually within them or is within the cytoplasm above or below the vacuoles and appears superimposed on them. In any event, the vacuoles observed as clear areas in ultra-thin sections do not correspond to any of the nuclear systems we know at present. In micro-organisms where the location of the real nucleus is known (for example, yeast cells) one notes that the nuclei are not in vacuoles but are embedded in the cytoplasm.

Although only 48-hr. cultures were included in the present work, and although there may be variation between species, we are of the opinion that the central core or zone of low electron density in *A. tumefaciens* represents a vacuolar system and is probably not the site of the bacterial nucleus or nuclear equivalent.

The work reported here was supported in part by a grant to the senior author from the Cancer Research Funds of the University of California while he was a visiting scientist in the Department of Plant Pathology, University of California, Riverside. Capacity of Extracts from Prestarved *Escherichia coli* to incorporate Thymidine into Deoxyribonucleic Acid

THE ability of a polyauxotroph, *Escherichia coli* strain 15_{T^-} (555–7), to synthesize deoxyribonucleic acid is temporarily lost following a period of incubation in a minimal salts–glucose medium containing thymine but no added amino-acids[1-4]. Moreover, when the starved cells are returned to a medium supplemented with amino-acid, a lag in synthesis of deoxyribonucleic acid is observed[2-4]. The restoration of an active deoxyribonucleic acid synthesizing system in these cells can be prevented by continued suppression of protein synthesis with chloramphenicol[3] or by exposure to X-rays[5]. One possible mechanism considered was that the enzyme or enzymes involved in deoxyribonucleic acid synthesis are lost or destroyed during the starvation period and that chloramphenicol and X-ray exposure prevent re-synthesis or reactivation of these components[3-5].

In a study of incorporation of thymidine labelled with tritium into deoxyribonucleic acid I have determined that polymerase and the kinases[6] responsible for phosphorylation of thymidine are present in the starved cell.

The extracts tested were obtained from cells broken in a French pressure cell. Intact cells and debris were pelleted by centrifugation at 10,000*g* for 20 min. Less than 10 colony-forming cells per mgm. protein were found in the extracts so obtained. The procedure for studying thymidine incorporation into deoxyribonucleic acid was a modified version of that used by Kornberg and collaborators[7,8]. Experiments 1 and 2 were conducted with batches of cells obtained from independent inocula. In the third experiment half an actively growing log-phase culture was used for preparation of the log-phase cell extract and the remaining portion put into medium deficient in amino-acid following harvesting and washing for preparation of the appropriate starved cell extract. Thus, in the latter experiment both cell suspensions were derived from the same culture batch. As can be seen in Table 1, the multi-enzyme system needed for thymidine incorporation was present in extracts obtained either from log-phase cells or cells which had been incubated for 90 min. at 37° C. in minimal medium supplemented with thymine but lacking the required amino-acids arginine, tryptophan and methionine ('starved cells'). These results are in contrast to the impaired *in vivo* deoxyribonucleic acid synthesizing capacity of the starved cells. I am investigating the possibility that thymidine incorporation in the absence of net deoxyribonucleic acid synthesis may occur *in vivo*.

Table 1. INCORPORATION OF THYMIDINE LABELLED WITH TRITIUM INTO DEOXYRIBONUCLEIC ACID

Experiment	Conditions	mμmoles ^{3}H-thymidine incorporated into deoxyribonucleic acid/mgm. protein*
(1) Extract from log phase cells	Complete system†	1·21
	Heated extract	0·01
	Minus adenosine triphosphate and phosphoglyceric acid	0·01
	Minus thymus deoxyribonucleic acid	1·02
(2) Extract from starved cells	Complete system	1·45
	Minus thymus deoxyribonucleic acid	1·35
(3*A*) Extract from log phase cells	Complete system	2·00
	Minus adenosine triphosphate and phosphoglyceric acid	0·02
	Minus the triphosphates of deoxyadenosine, deoxycytidine and deoxyguanosine	0·15
(3*B*) Extract from starved cells	Complete system	1·75
	Minus the triphosphates of deoxyadenosine, deoxycytidine and deoxyguanosine	0·20

* After incubation at 37° C. for 20 min., the reaction vessels were placed in ice and 0·2 ml. of carrier deoxyribonucleic acid (2·5 mgm./ml.) was added. The immediate addition of 0·5 ml. of cold 10 per cent perchloric acid stopped the reaction and precipitated the cold-acid insoluble material. After 10 min. the precipitate was broken up with a glass pestle and washed with a total of 2 ml. of cold distilled water. The precipitate was then centrifuged and the pellet dissolved in 0·2 *N* sodium hydroxide. The solution was reprecipitated with cold perchloric acid. This was repeated twice. The final precipitate was hydrolysed in 1 ml. of 5 per cent trichloracetic acid for 30 min. at 100° C. The hot-acid soluble supernatant was then assayed for radioactivity.

† The complete incubation mixtures (0·30 ml.) contained: 0·02 ml. of glycine buffer (1 *M*, pH 9·2); 0·02 ml. magnesium chloride (0·1 *M*); 0·03 ml. of 2-mercaptoethanol (0·01 *M*); 0·02 ml. each of the triphosphates of deoxyadenosine, deoxyguanosine and deoxycytosine (500 mμmoles/ml.); 0·02 ml. of thymus deoxyribonucleic acid (Sigma Corp.) that had been previously heated at 100° C. for 5 min. (0·5 mgm./ml.); 0·01 ml. of adenosine triphosphate (100 μmoles/ml.); 0·01 ml. of phosphoglyceric acid (0·05 *M*); 0·02 ml. of labelled thymidine (262 mμmoles/ml., 1·54 × 10^5 counts per min. per mμmole on the Packard liquid scintillation counter); extract containing 685 μgm., 585 μgm., 253 μgm., and 282 μgm. protein was added from experiments 1, 2, 3*A* and 3*B* respectively.

That the thymidine was being incorporated into the deoxyribonucleic acid by the multi-enzyme preparation from starved cells was shown by the observation that all the label was associated with the alkali-resistant portion of the cold-acid insoluble material. It is possible that formation of one or more of the necessary deoxyribonucleotides may be blocked in the starved cells. Gros and Gros working with other strains of *E. coli* requiring amino-acid reported the unimpaired capacity of amino-acid starved cells to form mononucleotides[1]. Whether this is true for the deoxyribotides remains to be determined. However, if the presence of thymidine phosphorylating enzymes is indicative of the presence of all enzymes involved in forming the triphosphorylated deoxyriboside substrates necessary for deoxyribonucleic acid synthesis, then I must look elsewhere to explain the discrepancy between the *in vivo* and *in vitro* studies. The possibility of an accumulation of inhibitors during amino-acid deficient growth must be considered. Perhaps there is an unstable protein needed *in vivo* to convert non-priming deoxyribonucleic acid into an active primer. In this work the extracts from both normal and starved cells were found to contain deoxyribonucleic acid capable of serving as primer (Table 1). This may not reflect the true *in vivo* situation since deoxyribonucleases and possibly other enzymes may be activated following rupture of the cell[7,8].

This work is continuing and will be published in more detail elsewhere.

Effect of the Peritoneal Fluid of the Guinea Pig on Strains of Enteric Bacilli

ALTHOUGH the complement-dependent bactericidal system of normal mammalian serum has been actively studied since the early descriptions of Nuttall[1] and Buchner[2], its role in native immunity is a matter of disagreement[3]. Recent reports indicate that strains of Gram-negative enteric bacilli isolated from patients' blood or from burns are ordinarily resistant to this system[4,5]. When equal numbers of a strain of *E. coli* resistant to this bactericidal effect and of one sensitive to it are injected into a rabbit, both strains ordinarily can be cultured from the blood stream 24 hr. following injection; but organisms from the resistant strain are 10–20 times more numerous[6]. There have been reports that strains of enteric bacilli resistant to the action of the complement-dependent system are more virulent for the mouse than are sensitive strains[7,8]. Such observations lead to the belief that bacterial strains sensitive to the action of this system are less likely to cause or maintain an infection than are resistant strains.

During the work on the bactericidal properties of human serum[4], it was noted that pleural or peritoneal transudates from patients with heart failure were active against strains sensitive to serum. This activity was considerably less than that of serum and could be destroyed by heating the transudates at 56° for 30 min.

One method of assessing the role of the complement-dependent system of peritoneal fluid appeared to be the intraperitoneal implantation of chambers containing sensitive and resistant bacterial strains. These chambers were designed to be permeable to body fluids but not to bacterial or mammalian cells[9]. The degree of sensitivity of strains to normal guinea pig and human sera was measured initially by determining the decrease in viable count following exposure of known numbers of bacteria to undiluted serum for 2 hr. at 37°. None of these bacterial strains was killed by heat-inactivated serum. The thirteen strains of enteric bacilli listed in Table 1 were used. Two sensitive strains and two resistant strains were ordinarily used as inocula in the four chambers inserted in each guinea pig.

Table 1. THE RELATIONSHIP OF THE SENSITIVITY OF BACILLARY STRAINS TO THE BACTERICIDAL EFFECT OF NORMAL SERA AND THEIR SURVIVAL IN INTRAPERITONEAL CAPSULES

Bacterial strain		No. bacteria killed/ml. serum in 2 hr.		Growth in intraperitoneal chambers
		Guinea pig	Human	No. times grew/No. trials
Klebsiella	15	160×10^6	160×10^6	0/5
Shigella	141	110×10^6	110×10^6	0/4
E. coli:				
	*A*9	170×10^6	170×10^5	0/4
	128	240×10^4	240×10^4	1/4
	*A*14	170×10^4	170×10^4	0/3
	182	168×10^4	168×10^4	4/14
	31	200×10^3	200×10^3	6/12
	*A*30	1,500	2,100	1/2
	108	140	0	14/15
	*A*13	98	143	2/5
	114	95	0	3/3
	102	54	0	12/15
	*A*29	19	0	3/3

Drum-shaped chambers about 6 mm. deep and 13 mm. in diameter were constructed from lengths of 'Tygon' tubing, the ends of which were covered with 'Millipore' membranes having a pore diameter of 0·45μ (ref. 9). 'Plexiglass' dissolved in ethylene dichloride was used as adhesive. The 'Millipore' membranes were autoclaved and the tubing boiled for 5 min. before the membranes were attached aseptically. Two No. 26 hypodermic needles were inserted through the wall of each chamber. One served as an outlet for air. Usually about 1,000 organisms suspended in physiological saline were injected through the other. The needle holes were sealed with a heated glass rod. Inocula up to 14,000 organisms were used in some experiments; but in any given experiment the numbers were approximately equal. Four of the chambers were then inserted into the peritoneal cavity of a guinea pig. These were removed at 48 or 72 hr. and the number of bacteria in each chamber determined by viable count. Sterility check on the membranes of the chambers at insertion and on removal showed no contamination, and no leakage.

Fluid from the chambers was examined by paper electrophoresis and the major serum fractions were present 24 hr. after the insertion. At 48 hr. the concentration of these fractions as estimated by their electrophoretic curves was about 60 per cent of that of guinea pig serum. Specimens from 40 chambers were examined by phase microscopy, and no mammalian cells were seen.

In every instance except two, the contents of the chambers either were bacteriologically sterile or showed a multiplication of the original inoculum to 1×10^8 to 1×10^9 organisms per chamber. In the two exceptions, the count had been reduced to less than fifty and these two instances are considered in the same category as the sterile ones

Table 1 lists the strains in their order of sensitivity to guinea pig serum *in vitro*. The numbers represent the maximum number of each strain killed by 1 ml. of undiluted serum. Close relationship between sensitivity *in vitro* to human serum and to guinea pig serum is apparent. A similar relationship between sensitivity to human serum and rabbit serum has been shown[8] and leads one to believe that results from experiments in one species may have implications for other species.

The column on the right in Table 1 shows the fate of the strains in the chambers. The very sensitive strains were killed whereas the most resistant strains usually multiplied. Strains of intermediate sensitivity multiplied in some instances but were killed in others. If a strain of intermediate sensitivity multiplied, it did so to the same extent as did resistant strains in the same animal.

These data serve to strengthen the belief that the complement-dependent bactericidal system is of importance in limiting the number of bacterial strains capable of surviving in tissue fluids *in vivo*.

SOIL SCIENCE

Domain or Turbostratic Structure of Clays

IT has been realized for some time that plate-shaped clay particles on drying tend to take up a parallel orientation with respect to one another. Further, Terzaghi[1] has indicated that groups of parallel particles behave as a single particle in suspension and has referred to these groups as 'clay clusters'. Aylmore and Quirk[2], in endeavouring to interpret the swelling of clay-water systems, have defined a 'domain' as a parallel arrangement of crystals. Coal research workers[3] have referred to a similar type of organization as 'turbostratic groups' since the elementary particles are arranged in a parallel fashion in groups and these groups are arranged in turbulent array. The present communication presents evidence for the nature of a domain and discusses the consequence of domain formation in swelling phenomena of clays.

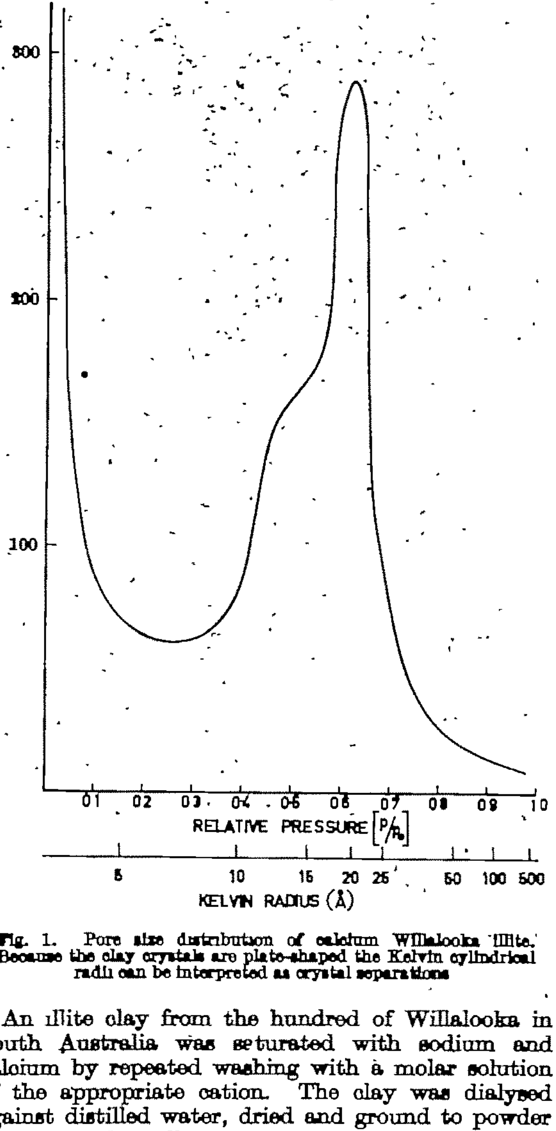

Fig. 1. Pore size distribution of calcium Willalooka illite. Because the clay crystals are plate-shaped the Kelvin cylindrical radii can be interpreted as crystal separations

An illite clay from the hundred of Willalooka in South Australia was saturated with sodium and calcium by repeated washing with a molar solution of the appropriate cation. The clay was dialysed against distilled water, dried and ground to powder which was then allowed to come to equilibrium with a relative vapour pressure of 0·96 before being compressed into cores[4]. These cores were wet up to *pF* 2 and dried in stages to complete desiccation over phosphorus pentoxide. Water and nitrogen isotherms were obtained using these cores. This illite, although low in potassium (potassium oxide, 4 per cent), gives no evidence of interstratification.

A complete adsorption–desorption isotherm of nitrogen was obtained at 78° K. The surface area of the clay calculated by the B.E.T. method was 150 m.²/gm. In Fig. 1 a plot of $dV/d(p/p_0)$ against p/p_0 is shown together with a scale to relate values of p/p_0 to the Kelvin cylindrical pore radius. The clay cores have a porosity of 18·8 c.c./100 gm. and at $p/p_0 = 0{\cdot}80$, 18·6 c.c./100 gm. of pores are filled, indicating that almost the entire porosity is contained in pores less than 42 Å. Kelvin radius. Since the plates of this mineral are 700 Å. across and this is large compared with the plate separation, the calculated Kelvin cylindrical radius can more properly be regarded as a measure of the plate separation. The pore peak in Fig. 1 shows that the clay mass can be regarded as a series of parallel crystals, the

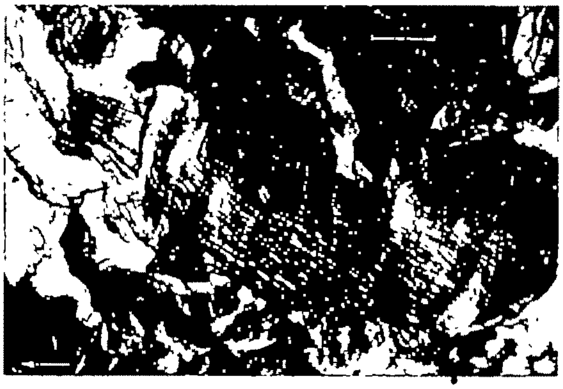

Fig. 2. Electron micrograph of the fracture surface of Willalooka illite core obtained using a replica technique. Arrows indicate the direction of uranium shadowing

separation of which varies between 10 and 30 Å. although closer approach may occur at a few points. This indicates that the pore space of this material is almost exclusively within domains, that is, there is very little interdomain porosity. An electron micrograph of a shadowed replica of the fracture surface of a dry clay core reveals the parallel arrangement of the clay particles and also indicates that there is considerable distortion of the crystals and domain structures undoubtedly caused by stresses set up in drying (Fig. 2).

In Figs. 3 and 4 the solution content–energy curves for sodium and calcium Willalooka illite at varying sodium chloride and calcium chloride concentrations are shown. Since the clay is largely organized on a domain basis it appears permissible to divide the solution content by the specific surface area to obtain a first approximation for the film thickness on the clay surface. When this is done, good agreement between Schofield's theory based on the Gouy–Chapman diffuse double layer and the experimental values for sodium-illite are found for 10^{-1}, 10^{-2} and 10^{-4} *M* sodium chloride concentration.

The remarkable insensitivity of the swelling of the calcium illite to calcium chloride concentration and the appreciable hysteresis in the water content suction curves indicates the non-applicability of diffuse double layer theory to the swelling of this material.

The explanation of the film thickness at *pF* 1 of 30 Å. even for distilled water and the presence of hysteresis lies in the existence of a potential barrier at a plate separation of < 60 Å. and the formation of a gel structure as the result of the relaxation of strains when sufficient liquid is present in the clay matrix. The limited swelling cannot be ascribed to cementing materials; when the sodium illite, swollen in distilled water, is converted to a calcium illite and dried, identical swelling behaviour to the calcium illite prepared directly from the natural material is observed. MacEwan[4] has suggested that coulombic attractive forces exist up to plate separations of 30 Å., at which separation he envisaged the formation of separate double layers by each particle. It seems reasonable to conclude that calcium illite does not overcome this barrier, and that for sodium illite the barrier is overcome, giving rise to high solution contents which are dependent on the sodium chloride concentration. The similarity of this behaviour to that of sodium and calcium montmorillonite[5] is striking and supports the suggestion that a domain structure in some respects resembles a montmorillonite crystal. It is also important to note that on heating to 400° C. the sodium illite swells very little but still retains its exchange capacity of 0·41 m.equiv /gm.

One difficulty in interpreting the water content of a clay in terms of the film thickness developed by the clay particle is that, on wetting, relaxation of strains[6] leads to the formation of a gel structure so that it is difficult to separate that water which is

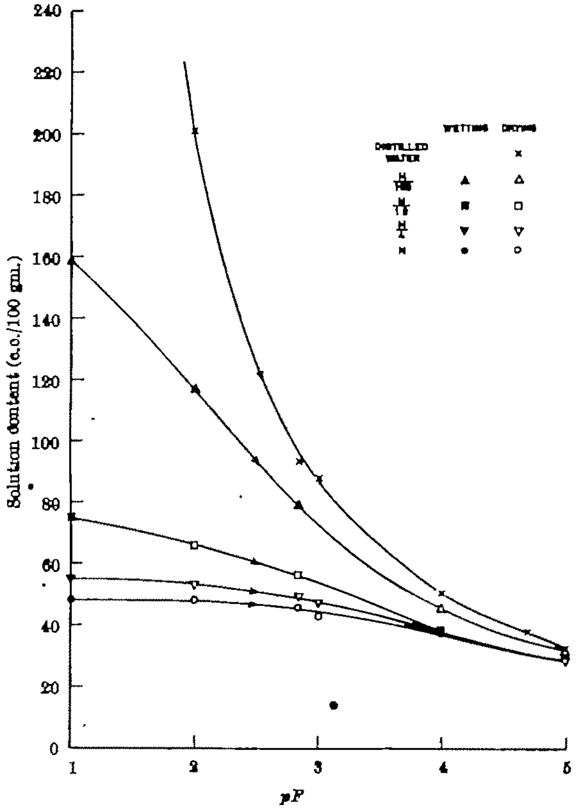

Fig. 3. Solution content–energy curves for sodium Willalooka illite at various electrolyte concentrations (sodium chloride). Note that *pF* indicates only the logarithm of the hydrostatic suction in cm. of water

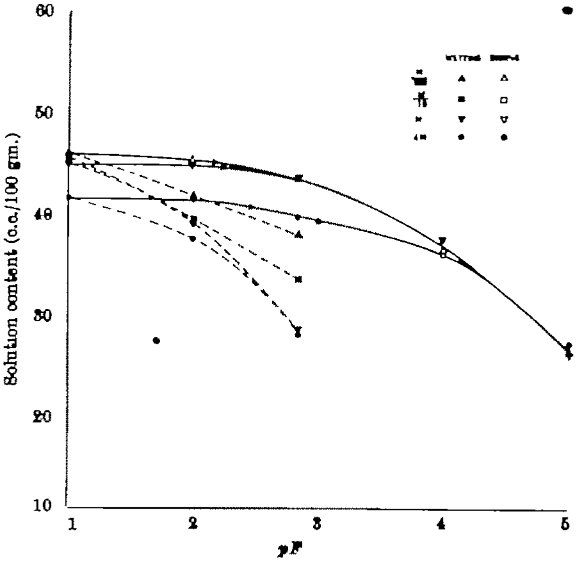

Fig. 4. Solution content–energy curve for calcium Willalooka illite at various electrolyte concentrations (calcium chloride)

directly associated with the clay surfaces from water which is simply enmeshed within the gel structure. Enmeshed water can be regarded in the following way. When a rigid porous material initially filled with liquid dries out under a falling vapour pressure, pores (capillaries) of particular dimensions will empty at a particular vapour pressure. The remaining liquid is held under a hydrostatic suction which is transmitted to the walls but, as each pore empties, stresses on the walls due to this cause will fall to zero. If, however, the material is easily deformed, the suction in the liquid will cause a reduction in the size of the pore, and evaporation will be delayed until a lower vapour pressure is reached, by which time the suction has further increased. The mechanism has been postulated by Barkas[7] for wood-gels, but is clearly applicable to the interpretation of gel structures and hystereses in clay–water systems.

In conclusion, it is necessary to comment on two recent papers which have overlooked, wholly or in part, suggestions put forward at an earlier date by us. Greacen[8], in discussing the swelling of calcium montmorillonite in terms of the critical voids ratio line, has used a surface area of 800 m.^{2}/gm. and has not adequately taken into account the presence of a gel structure. Blackmore and Warkentin[9] have also claimed that their results support the existence of diffuse double layers on the external surface of montmorillonite crystals. However, they too have not considered the possibility that much of the water retained by their clay was enmeshed in a gel structure. Further, Norrish[10] and also Blackmore and Warkentin[9] have noted a collapse of swollen crystals or a condensation of elementary silicate sheets of sodium montmorillonite to give a 19 Å. spacing in the presence of dilute calcium chloride solutions. This situation indicates that attractive forces in calcium clay systems must be such that diffuse double layers do not readily form.

The results discussed here, and those obtained for kaolinites and montmorillonites which will be presented elsewhere[11,12], indicate that diffuse double-layer formation is not of any great significance for the swelling of calcium clays. Diffuse double layers may exist for crystals of calcium clays in a suspension, but this is doubtful in view of the negative adsorption results obtained for an illite[13].

We are indebted to Mr. D. M. Hall, of the Department of Scientific and Industrial Research Dominion Physical Laboratory, for obtaining the electron micrograph.

VIROLOGY

Polyphenol Oxidase Activity of *Nicotiana glutinosa* Leaves infected with Tobacco Mosaic Virus

WHEN local necrotic lesions appeared on the leaves of *Nicotiana glutinosa* L. infected with tobacco mosaic virus, but not before, the respiration-rate increased[1]. The same phenomenon was observed on some other host–virus combinations which produced local necrotic lesions[2]. In these cases, it seems that the increased rate of respiration varies with various developmental stages of the necrotic lesions, namely, with degrees of brownish discoloration of leaf tissue due to the virus infection. When the tissues of the tobacco plant are injured, the polyphenol substances are oxidized and then polymerized by polyphenol oxidase[3]. Therefore the polyphenol oxidase activity of leaves bearing necrotic lesions has been compared with that of healthy leaves.

The half-leaves of *N. glutinosa* plants were inoculated mechanically with tobacco mosaic virus and healthy control halves were treated with healthy tobacco leaf sap. Local lesions became visible the second day after inoculation at 20° C. Leaves were harvested on the day following inoculation; when no lesions appeared, the second and the third day after inoculation. Polyphenol oxidase activity was measured in crude enzyme preparations: acetone powder prepared from healthy and infected half-leaves, by the use of Warburg respirometer. The results are expressed by µl. oxygen absorbed by acetone powder (30 mgm. dissolving in solution containing 0·05 *M* phosphate buffer, *p*H 7·0, and 0·2 *M* sucrose) on addition of catechol (0·05 *M*) as a substrate at the rate of once an hour and once every 2 hr. in the case of gallic acid (0·05 *M*). These values have been corrected for autoxidation values and represent the mean value of several experiments. Oxygen consumption in each experiment varied so much according to the leaves chosen or preparative procedure of acetone powder that the standard error of the difference between the values for healthy and infected leaves was calculated (Table 1).

Table 1. POLYPHENOL OXIDASE ACTIVITY OF *N. glutinosa* HALF-LEAVES INOCULATED WITH TOBACCO MOSAIC VIRUS AND OF HEALTHY HALVES

Days after inoculation	Polyphenol oxidase activity Infected	Healthy	Ratio Inf. Healthy	*S.E.*	No. of determinations
Catechol substrate					
1	31·8	31·2	1·02	±1·44	5
2	51·7	35·9	1·44	±1·29	6
3	70·4	43·9	1·60	±6·60	6
Gallic acid substrate					
1	12·1	15·3	0·79	±3·18	5
2	17·5	14·5	1·21	±2·80	6
3	27·1	12·6	2·15	±3·66	6

As shown in Table 1, a considerable increase in activity of polyphenol oxidase was found the third day after inoculation by using either catechol or gallic acid as substrate. In contrast, there was no increase in the activity on the day following inoculation, having no visible lesions, on either substrate. On the second day, when faint black spots had become visible, the ratio of the activity between infected and healthy was 1·44 by using catechol as substrate, and its difference was highly significant, while the difference is not significant at the 5 per cent level in the case of gallic acid although the ratio is 1·21.

In spite of much research, present knowledge of the precise nature of phenol oxidase is limited, and its role in cellular respiration is not as yet clear[4]. It seems, however, that the enhanced activity of polyphenol oxidase plays an important part in browning of plant tissue or hypersensitive defence reaction in both fungal and viral infection[5]. It is unknown whether or not the polyphenol oxidase is a catalyst mediating the final reaction with oxygen in cellular respiration of *N. glutinosa* leaves. The findings, however, that no increase in the activity is detected on the following day after inoculation and the increased rate of the third day is higher than that of the second day were apparently consistent with the results obtained by Yamaguchi and Hirai in the respiration measurement of *N. glutinosa* leaf disks infected with the same virus[1]. Recently, Solymosy *et al.*[5] offered clear-cut evidence that the stimulated activity of phenol oxidase was the immediate cause of lesion formation, by using the technique of administration of compounds capable of reducing quinones or inhibiting lesion formation. This seems to explain the biochemical mechanism of lesion formation. We cannot explain, however, the cause of the parallelism between increased oxygen consumption in infected leaf disks and increased polyphenol oxidase activity during lesion development. This raises the problem of the nature of terminal oxidase in infected tissues.

We are indebted to Prof. Tokuzo Hirai for valuable discussions.

Direct Infra-Red Spectral Analysis of the Cucumber Mosaic Virus Infection Process

INFRA-RED spectroscopy may provide a means of following biochemical changes which occur in tissues as a result of virus infection, if induced spectral changes can be detected and related to the structure of the absorbing compounds.

The upper surfaces of fully expanded cotyledons of cucumber seedlings were dusted with 'Carborundum' and inoculated with a small sponge rubber pad moistened with tissue homogenates of tobacco plants infected with cucumber mosaic virus. Identically grown control plants in separate pots were dusted with 'Carborundum' and rubbed with virus-free buffer in the same manner. Control and virus-inoculated plants were held in a growth chamber with a 16-hr. day at 28° C. and an 8-hr. night at 20° C.

Lower epidermis was stripped from three infected and from three normal plants at daily intervals following inoculation. Adhesive 'Cellophane' tape was punched with a $\frac{1}{4}$-in. circular paper-punch and then placed in contact with the epidermis. The tape was peeled from the mesophyll tissue carrying an intact epidermal layer covering the punched-out area. The tissues were allowed to dry in the normal laboratory atmosphere of about 20–30 per cent humidity and were analysed 24–48 hr. later with a Perkin Elmer model 21 infra-red spectrophotometer. The spectrum of a normal lower epidermis from a cucumber cotyledon plotted against air in the reference beam is shown in Fig. 1.

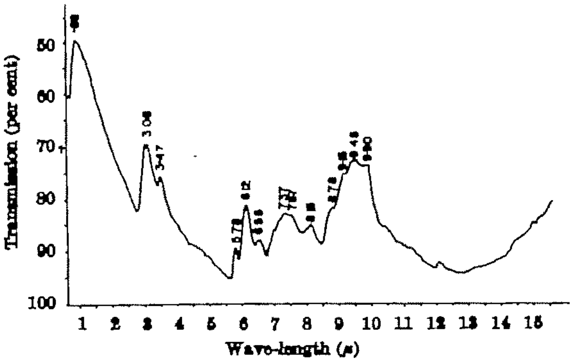

Fig. 1. Infra-red transmission through dried, normal cucumber cotyledon lower epidermis. Wave-lengths of principal peaks are identified

The analytical method used for detecting virus-induced changes was differential double-beam analysis with normal epidermal specimens in the reference beam and virus-infected epidermal specimens in the sample beam. The instrument then plotted the difference between the infected and normal specimens at all wave-lengths from 1 to 15μ. The recorder pen was adjusted to near mid-scale on the chart paper so that induced excesses and deficiencies could both be recorded as deviations from the I_0 (base line) of the instrument. These deviations were plotted linearly from I_0 in terms of percentage of the transmission of the normal tissue. Each of the infected tissues was compared with each of the normal tissues collected at the same time. The recorded spectral curves of each day's analyses were superimposed to give maximum coincidence of points. Median values were drawn for the superimposed curves and were plotted as values representative of the daily virus-induced changes. The daily median values plotted from two successive experiments were remarkably similar, indicating that the analytical method was reproducible. The results from both experiments are combined in Fig. 2 to show the progressive changes induced by the virus infection in the tissues as detected by the methods used.

Interpretation of the results presented in Fig. 2 is complicated by the numerous cellular reactions occurring within epidermal cells during the infection. Synthesis of virus nucleic acid and protein is probably accompanied by degradative reactions. Translocation of carbohydrates and possibly amino-acids, purines and pyrimidines to the halophytic epidermal cells may be altered by the changed rates of utilization of these compounds in cells infected by virus. Virus formation and side reactions may produce accumulated intermediate or end products that are not used in producing virus. The spectrophotometric changes

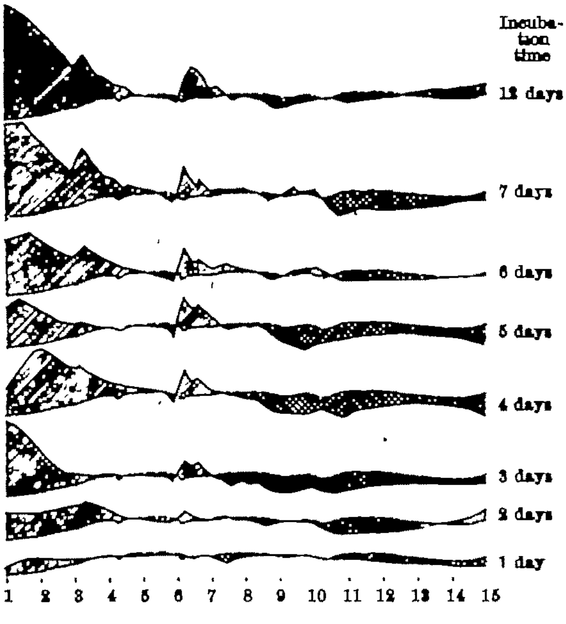

Fig. 2. Progressive changes in infra-red absorption of lower epidermis of cucumber cotyledons induced by the cucumber mosaic virus infection process (averaged values of two experiments). Full line, graphically determined median value for comparisons of three virus-infected with three normal epidermal strips; broken line, I_0 (base-line of the instrument); dark shading, greater than normal absorption; light shading, less than normal absorption

observed during the course of an infection represent the resultant effects that all the above processes have in adding to or decreasing the total number of chemical bonds that are responsible for absorption at each wave-length.

Increased spectral absorption in the infected tissues reflects an increased accumulation of certain chemical bonds that may be the result of increased translocation or of synthesis. A decreased spectral absorption in the infected tissues reflects losses of certain chemical bonds probably as a result of degradation reactions or perhaps by translocation.

The peptide linkage is known to give rise to strong absorption bands at 6·1 and 6·5μ (ref. 1). Because increased absorption at 6·5μ did not occur until the third day, it appears that a significant increase in peptide linkages did not occur until this time. The absorption at this wave-length continued to increase on the fourth and fifth days, but fell to a lower level on the sixth and seventh days. It is probable that this increase in peptide linkages reflects a comparable increase in proteins.

Nucleic acids and proteins both absorb strongly in the 3- and 6-μ ranges. It is possible that the absorption seen at these wave-lengths on the second day is caused by increases in nucleic acids. Nucleic acids also absorb strongly in the 9–9·5μ range[2]. On the second day there is a slight excess in this spectral region. On the third, fourth and fifth days marked deficiencies occur in this range and then on the sixth and seventh days excessive absorption occurs again. It is interesting to note that the absorption in the 9–9·5μ region appears to vary inversely with the absorption at 6·5μ. The results suggest that a cyclic variation has occurred in which nucleic acids build up and then fall during a period in which proteins are increased. Then when protein-levels fall on the sixth and seventh days nucleic acid-levels rise.

The relation of nucleic acid to protein synthesis is not well understood. Perhaps a comparison with studies of nucleic acid synthesis in virus-infected bacterial cells is noteworthy. An exponential increase of protein, ribonucleic acid and deoxyribonucleic acid occurs in a logarithmically growing population of bacterial cells. However, at the time of the inoculation of *E. coli* with T_2 bacteriophage the synthesis of bacterial components stops quickly and the cellular machinery is devoted to the synthesis of viral protein and viral deoxyribonucleic acid[3]. Astrachan and Volkin[4] have shown with tracer studies that a burst of synthesis of ribonucleic acid occurs before the formation of virus proteins. It is postulated that the synthesis of ribonucleic acid is a necessary prerequisite for the formation of the proteins essential to virus formation.

The results in Fig. 2 suggest that other reactions are occurring, but no attempt will be made at the present time to postulate these. Experiments are now in progress in which this type of analysis is being applied to the study of the earliest detectable events in the infection process.

The work reported in this communication was supported, in part, by research grant No. *AT*(11–1)-80 Proj. 3 from the United States Atomic Energy Commission.

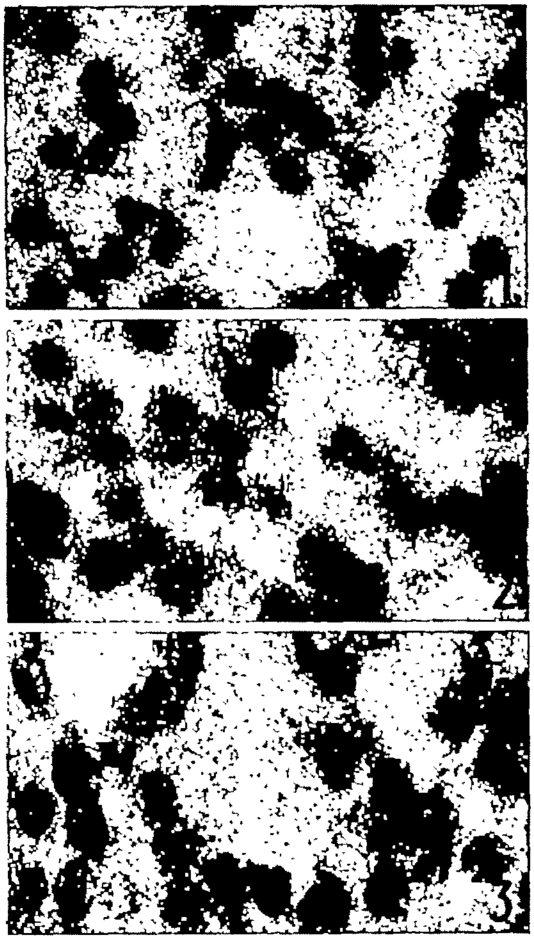
Site and Nature of Adenovirus Nucleic Acid

THE effects of specific nuclease digestion on the morphology of the Rous virus, as observed with the electron microscope, established recently that this agent's nucleoid contained a substantial amount of ribonucleic acid[1,2]; the type of nucleic acid was confirmed at the same time by cytochemical studies[3].

Similar methods have now been used with type 5 adenovirus. The virus was grown in HeLa cell cultures[3], and particles were isolated from them by a fluorocarbon separation technique[4,5] followed by high-speed centrifugation. Samples of the particle-containing zones of the resulting pellets were used for the work and were first sectioned for electron microscopy in order to check their homogeneity[6]. Biological tests were combined with these experiments and served to indicate the viral nature of the particles[6].

Thereafter, other samples of pellets containing the virus were treated with nucleases following fixation with potassium permanganate[7], a fixative known to permit subsequent digestion of nucleic acids by such enzymes[8]. The nucleases were applied in many ways; but specific changes in virus morphology were only



Figs. 1–3. Electron micrographs of thin sections of permanganate-fixed adenovirus particles treated in various ways. All the particles were exposed to a preliminary incubation at 37° C. for 2 hr. in buffer at *p*H 9 containing 30 per cent alcohol, and show some degree of swelling as compared to examples prepared directly. × 75,000

Fig 1. Control particles given a second incubation in 30 per cent alcohol containing 0·003 *M* magnesium chloride; the dense nucleoids are very evident

Fig. 2. Particles which had been exposed to ribonuclease at *p*H 7 (1 mgm. per ml.) during a second incubation in 30 per cent alcohol. No change has taken place in the density of the nucleoids

Fig. 3. Particles treated with deoxyribonuclease (1 mgm. per ml.) and 0 003 *M* magnesium chloride in 30 per cent alcohol during a second incubation. The nucleoids have been digested

observed after the following procedure. Samples of virus fixed in iced permanganate were placed in iced 30 per cent alcohol and brought to room temperature; they were then incubated for 2 hr. at 37° C. in Michaelis veronal buffer at *p*H 9 containing 30 per cent alcohol. After this the samples were divided into three groups and were incubated again in 30 per cent alcohol containing respectively 1 mgm. per ml. ribonuclease at *p*H 7, the same quantity of deoxyribonuclease together with magnesium chloride at a concentration of 0·003 *M* or, as a control, a similar concentration of the salt but no enzyme. At the end of this second incubation all the samples were dehydrated, embedded in *n*-butyl methacrylate and sectioned for electron microscopy.

Exposure to the alkaline buffer caused some degree of non-specific swelling of all particles as compared with examples prepared directly, while in the control preparations treated with enzyme-free medium after the buffer, no other structural change was seen (Fig. 1). A similar lack of change was found in particles treated with ribonuclease during the second incubation, the density of the nucleoids being well preserved (Fig. 2). In marked contrast, the nucleoids were digested from particles incubated with deoxyribonuclease after alkaline buffer (Fig. 3). The effect of the buffer was probably to degrade the outer coat of the particles in the manner already reported for mild alkalis[8,9], so allowing subsequent penetration by deoxyribonuclease.

These results demonstrate that the adenovirus contains much deoxyribonucleic acid, thus substantiating earlier inferential evidence[10], and also establish the location of this material in the nucleoid. A full account of this work will be given elsewhere[11] together with the confirmatory results of concomitant fluorescence microscopy tests for nucleic acids[12,13].

ARCHÆOLOGY

The Enkomi Silver Cup

In *Nature* of May 28, p. 676, reference is made to a nielloed silver cup of 1400 B.C. from Enkomi, Cyprus. To encounter a nielloed article of such an early date would indeed be a discovery of importance, since, so far as we are aware, no one has proved the use of niello as a means of decoration before the second century A.D. (ref. 1). There is, however, no evidence for the presence of niello on this cup, as we were able to demonstrate at the time the cup was being restored. The paper dealing with this[2] shows clearly that the only basis the author had for assuming the powdery material surrounding the gold ornamentation to be niello was that it was black.

It will be apparent, therefore, that the Enkomi cup should be made available for further scientific study; but in the meantime we should like to point out that the only conclusion that can be arrived at from the evidence reported in the paper[2] is that the Enkomi silver cup was inlaid not with niello, but with copper. It is pertinent to remark that, when last seen by us, the handle of the cup still retained some of its copper inlay.

G. F. Claringbull
A. A. Moss
British Museum (Natural History),
London, S.W.7. July 4.

[1] Moss, A. A., *J. Int. Inst. Preserv. Museum Objects*, 1, 49 (1953).

[2] Plenderleith, H. J., technical report in C. F. A. Schaeffer's "Enkomi-Alasia", 381 (Paris, 1952).

THAT the Enkomi silver cup exhibits many fascinating points of technique no one will deny. The suggestion that the black is derived from an inlay of copper is interesting, especially coming from the Department of Mineralogy of the British Museum (Natural History), and it is clear that such a copper-inlay technique would be likely to facilitate manufacture; but, in the absence of the inlays, its presence would be difficult and might even be impossible to prove. The cap at the extremity of the 'wish-bone' handle, referred to above, was scraped and the freshly exposed surface appeared coppery, but whether due to inlay or to staining of the silver alloy (that is, by niello) was not determined. Dr. Claringbull, who examined scrapings by spectrograph, could detect silver, copper and gold only. It is admitted that to obtain a *representative* sample of the black material in question from the bowl, without causing damage, was found to be most difficult. A further examination by X-ray diffraction of a second tiny specimen that was submitted yielded nothing fresh.

The features that led me to consider the Enkomi cup had been decorated with niello may be summarized: black patterns lustrous or splendent and enamel-like; where damaged, brittle and in one case appearing as a charcoal-like powdery stain subsisting from antiquity in contact with massive copper chlorides and carbonates; where undamaged, forming a perfect tracery of shiny jet-black mass-and-line ornament in a groundwork of bright metallic silver; the perfection of line and lustre survived immersion for 20 min. in commercial formic acid (1 : 2 parts water, by vol.), at boiling temperature, without any sign of loss. The gold-foil patterns that had been applied to this black material were in no way deformed, as one might have expected them to be, had they been mounted on copper inlays that would certainly have become swollen by oxidation during 2,000 years of burial. The cavities cut in the silver to contain the black decoration, where undamaged, were filled flush with the surface contour and the black material did not appear to have increased in bulk. If the results of the X-ray crystallographic examination were considered to be in doubt because of the possible inadequacy of the sample, the above observations—difficult to explain otherwise—had to be taken as straw in the wind suggesting the use of niello.

The weak point in the argument for niello is that although chlorides were present in quantity in the incrustation, no trace of sulphides could be detected. For this reason I agree that the case must be taken to be not proven as regards the presence of stromeyerite and acanthite; and, having regard to the importance of the matter, I would agree further that a re-examination is desirable. I suggest, however, that as we have now a new theory, some preliminary work should be done on black lustrous copper minerals (as exemplified, for example, in Tang mirrors) to determine how far the black compounds can survive treatment with hot formic acid without losing lustre, shape or quality, before contemplating further operations on the cup itself.

MISCELLANY

Cost of Scientific Periodical Publications

I AM writing with reference to the paragraph under the above heading which appeared in *Nature* of April 9, p. 124.

The periodicals mentioned are not similar in matter per page, since some of them contain considerable amounts of what is classed as 'difficult' setting by printers, and this has an appreciable effect on production costs. While it may be broadly true to say that a reduction in price leads to increased circulation, the optimum circulation obviously depends on several other factors; for example, the number of people engaged in research in a particular field. The journal which has the backing of a scientific society is in an advantageous position in that it has a guaranteed circulation to members of that society, as well as a subsidy in most cases.

The figures quoted in the table are approximately correct for 'library subscription rates' of the Pergamon Press journals mentioned, although, on the basis of the volumes completed on 1959 subscriptions, the price of *Physics and Chemistry of Solids* is 3·7*d.* per page (not 4·1*d.*), and that of *Reactor Science* is 8·2*d.* per page (not 8·9*d.*). However, the table as published is not the whole story so far as Pergamon Press subscription prices are concerned. Pergamon Press, in order to ensure maximum dissemination and to encourage individual scientists to own their own journals, have a specially low subscription price for private individuals, and the effect of comparing these subscription rates against the journals published by other publishers listed in the table is as follows:

Title	Source	Publisher	Price per page
Tetrahedron	U.K.	Pergamon Press	0·7*d.*
Journal of Inorganic and Nuclear Chemistry	U.K.	Pergamon Press	0·9
Journal of the Chemical Society	U.K.	Chemical Society	1·0
Physics and Chemistry of Solids	U.K.	Pergamon Press	1·0
Chemical Reviews	U.S.A.	American Chemical Society	1·2
Journal of Soil Science	U.K.	Oxford University Press	1·3
Chemical Engineering Science	U.K.	Pergamon Press	1·4
Information and Control	U.S.A.	Academic Press	2·0
Philosophical Magazine	U.K.	Taylor and Francis	2·2
Biochemie	Holland		2·25
Fuel	U.K.	Butterworth	2·5
Journal of Electronics	U.K.	Taylor and Francis	2·8
Chemical Abstracts	U.S.A.	American Chemical Society	3·0
Reactor Science	U.K.	Pergamon Press	4·1

Since this note was written, an amicable and constructive meeting has taken place between representatives of the Pergamon Press and the Standing Conference of National and University Libraries and the Library Association; the latter, although they now have a better appreciation of the reason for the Pergamon Press price differential policy, nevertheless still object to the fact that libraries should have to pay the higher, multi-user price.

I. R. MAXWELL

Headington Hill Hall,
Oxford.

FORTHCOMING EVENTS

Monday, September 19

INSTITUTE OF METAL FINISHING (at the Northampton College of Technology, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. D. R. Weiner: "Decorative and Electronic Applications of Gold Plating".

Tuesday, September 20

SOCIETY FOR ANALYTICAL CHEMISTRY (at the Royal Institution, 21 Albemarle Street, London, W.1), at 11 a.m.—Meeting on "The Chemist and Food Quality".

Wednesday, September 21—Friday, September 23

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS AND POLYMER GROUP (in the William Beveridge Hall, Senate House, and the Assembly Hall, Institute of Education, University of London), at 9.30 a.m. daily—Symposium on "High Temperature Resistance and Thermal Degradation of Polymers".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

PRINCIPAL (graduate, or equivalent qualification, with teaching, administrative and industrial experience) OF HACKNEY TECHNICAL COLLEGE, London, E.8—Education Officer (FE3a/T/2066/9), London County Council, County Hall, London, S.E.1 (September 23).

RESEARCH ASSISTANT (with experience of research work in physical chemistry or physics and preferably with a Ph.D. degree in one of these subjects) IN THE DEPARTMENT OF CHEMISTRY, to continue work on a programme, under the general direction of Dr. S. J. Gregg, on the reaction of gases with metals at elevated temperatures. The techniques include measurement of the sorption of gases and the use of the vacuum microbalance and of radioactive tracers; special attention is paid to the part played by the film of reaction product—The Secretary, The University, Exeter (September 24).

RESEARCH FELLOW (preferably with experience in rocket or satellite instrumentation) IN PHYSICS, for research on primary cosmic rays using instruments carried in artificial earth satellites—The Secretary and Registrar, The University, Southampton (September 28).

ASSISTANT ANALYST (science graduate with some training in biochemical methods), in an experimental cytology unit working mainly on neurobiological problems—The Professor of Pathology, School of Medicine, Leeds 1 (September 30).

BACTERIOLOGIST, Assistant Experimental Officer grade (with a pass degree with bacteriology as main or subsidiary subject, or equivalent qualification), in the Humber Laboratory, Kingston-upon-Hull, to assist in research on bacteriological aspects of handling, processing and preservation of fish and fish products, together with certain fundamental studies of marine microbiology—The Ministry of Labour, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting G323/0A (September 30).

HEAD (with high academic and professional qualifications in mechanical or electrical engineering together with appropriate industrial, teaching and administrative experience) OF THE ENGINEERING DEPARTMENT—The Registrar, Flintshire Technical College, Connah's Quay, near Chester (September 30).

SENIOR RESEARCH FELLOW IN PHYSICS at the University of New England, Armidale, N.S.W., to take part in a research programme to study the action of very powerful beams of gyro-waves on the ionosphere—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (September 30).

RESEARCH FELLOW IN PHYSICS at the University of Tasmania, for work with a group which is active in the field of intensity variations and associated solar-terrestrial phenomena, using counting techniques developed for the I.G.Y.—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (September 30).

LECTURER IN PHARMACOLOGY in the Department of Pharmacology and Therapeutics—Joint Clerk to the University Court, Queen's College, Dundee (October 1).

VETERINARY SURGEON (preferably a recent graduate with some practical experience and an interest in the application of chemical methods to the investigation of animal diseases) in the Agricultural Research Council's Experimental Pathology Department, Institute of Animal Physiology, to assist the Clinical Pathologist—The Secretary, Institute of Animal Physiology, Babraham, Cambridge (October 1).

LECTURER IN THE DEPARTMENT OF PHYSIOLOGY—The Secretary, The University, Aberdeen (October 3).

SCIENTIFIC ASSISTANT, for the maintenance of physical instruments, including spectrophotometers and radiochemistry equipment—Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (October 8).

JUNIOR RESEARCH FELLOW or RESEARCH FELLOW IN THE DEPARTMENT OF BOTANY, University College, Ibadan, Nigeria, for research into the biology of the parasite Striga—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (October 10).

ASSISTANT LECTURER (with special qualifications in physical chemistry) IN PHYSICAL CHEMISTRY—The Registrar, The University, Manchester 13 (October 15).

LECTURER IN PHYSIOLOGY at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (October 15).

PRINCIPAL (with high academic qualifications and appropriate educational and administrative experience)—R. H. Currell, F.C.A., Northern Polytechnic, Holloway, London, N 7 (October 15)

PROFESSOR AND HEAD (with academic qualifications and research or development experience appropriate to a postgraduate department studying gas turbines, jet propulsion engines and rockets, with an increasing emphasis on high temperature problems and nuclear power) OF THE DEPARTMENT OF AIRCRAFT PROPULSION—The Principal, The College of Aeronautics, Cranfield, Bletchley, Bucks (October 15).

RESEARCH CHEMIST or BIOCHEMIST (honours graduate in science or agricultural science) IN THE DAIRY RESEARCH SECTION, Commonwealth Scientific and Industrial Research Organization, Melbourne, Australia, to take part in an expanded programme of research on dairy manufacture—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2 (October 15).

SENIOR LECTURER and LECTURER IN MATHEMATICS at the University of the Witwatersrand, Johannesburg—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (October 15).

SENIOR LECTURER (with an honours degree, and preferably a higher degree in electrical engineering with specialization in electronics) IN ELECTRICAL ENGINEERING at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, October 15).

SENIOR RESEARCH ASSISTANT, and EXPERIMENTAL OFFICERS (2), to work under the direction of Prof. G. Gee on the physical properties of high polymers—Prof. G. Gee, Department of Chemistry, The University of Manchester, Oxford Road, Manchester 13 (October 15).

CHAIR OF MEDICAL RADIOBIOLOGY in St. Bartholomew's Hospital Medical College—The Academic Registrar, University of London, Senate House, London, W.C.1 (October 20).

SENIOR NUFFIELD RESEARCH FELLOW (graduate in either medicine or science, and with several years research experience) IN THE DEPARTMENT OF MICROBIOLOGY—The Registrar, University of Adelaide, Adelaide, South Australia (October 20).

DIRECTOR (with a sound scientific training and with the ability to co-operate with scientific personnel, the administrators and the occupiers of the tussock and mountain lands) OF THE TUSSOCK GRASSLANDS AND MOUNTAIN LANDS INSTITUTE, Canterbury Agricultural College, Lincoln, New Zealand—Mr. H. G. Hunt, Registrar, Lincoln College, Christchurch, New Zealand (October 22).

LECTURER (with an honours degree in philosophy and experience in teaching and research) IN CHARGE OF THE TEACHING OF PHILOSOPHY at the University of Malaya, Kuala Lumpur—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Kuala Lumpur and London, October 22).

CHAIR OF MATHEMATICS—The Registrar, The University, Hull (October 31).

FOUNDATION CHAIR OF NUCLEAR ENGINEERING in the University of New South Wales, Kensington, New South Wales, Australia—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2 (Australia, October 31).

SENIOR LECTURER IN PHYSICS at the Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (October 31).

SENIOR LECTURER or LECTURER (with an honours or higher degree in science or engineering and with teaching and research experience in the fields of the physics of solids, the mechanics of solids or solid state chemistry) IN ENGINEERING MATERIALS at the University of Melbourne, for duties including lectures and supervision of laboratory classes for second and fourth year engineering students who are required to study engineering materials on the basis of solid state physics and chemistry—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (November 14).

PROFESSOR AND HEAD OF THE DEPARTMENT OF AGRICULTURAL ECONOMICS AND PROVINCIAL AGRICULTURAL ECONOMIST—The Registrar, The University, Nottingham (December 1).

ASSISTANT PROFESSOR (preferably with an interest in anaesthesia) OF PHARMACOLOGY—Prof. J. G. Aldous, Department of Pharmacology, Dalhousie University, Halifax, N.S., Canada.

ASSISTANT PROFESSOR (with Ph.D. or M.B. degree) IN PHARMACOLOGY—Prof. M. F. Murnaghan, University of Ottawa, Ottawa, Ontario, Canada.

ASSISTANT PROFESSOR or ASSOCIATE PROFESSOR (PHYSIOLOGIST, with an M.D. or Ph.D. degree and capable of independent research) IN THE DEPARTMENT OF PHYSIOLOGY—Prof. M. Bernak, University of Ottawa, Ottawa, Canada.

CHAIR OF AGRICULTURE in the Faculty of Agriculture, University College of the West Indies, St. Augustine, Trinidad—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

GEOLOGIST (with a degree in geology, general experience in geology and geophysics and a knowledge of the occurrence of ground water) with the Government of Kenya, for duties including the location of sites for water boring, geological mapping with special reference to occurrence of ground water and general investigations connected with engineering problems—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.112/7/044/01.

INTERNATIONAL WOOL SECRETARIAT RESEARCH FELLOW (with a degree in physics or physical chemistry, and with some research experience), to undertake work on the structure of protein fibres generally and wool in particular—Dr. F. Happey, Head of the Department of Textile Industries, Bradford Institute of Technology, Bradford.

LECTURER (with an honours degree in chemical engineering or corporate member of the Institution of Chemical Engineers, with experience in research and in the operation and supervision of full-scale chemical plant) IN CHEMICAL ENGINEERING—The Registrar, The University, Nottingham.

LECTURER (with a good honours degree and practical experience, with an interest in fluid motion and its technical applications) IN FLUID MECHANICS—Prof. C. M. White, Imperial College of Science and Technology, London, S.W.7.

LECTURER (with qualifications in mineralogy and petrology and an active interest in pre-cambrian rocks and ore deposits) IN GEOLOGY at the University of Khartoum—The Registrar, University of Khartoum, care of Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

MASTER TO TEACH PHYSICS: and a MASTER TO TEACH BIOLOGY—The Head Master, King's College School, Wimbledon, London, S.W.19.

PLANT PATHOLOGIST (with a good honours degree in a biological science, with postgraduate experience in research or advisory work in plant pathology) in Tanganyika, for research and specialist advisory services in plant pathology—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/8/08/C1.

PRINCIPAL (male, with appropriate qualifications and experience) OF THE DUDLEY AND STAFFORDSHIRE TECHNICAL COLLEGE—The Chief Education Officer, Education Offices, 3 St. James's Road, Dudley, Worcs.

RESEARCH ASSISTANT (with at least two years electronics experience) AT THE NUFFIELD RADIO-ASTRONOMY LABORATORIES, Jodrell Bank, for development and construction of low noise parametric amplifiers for use with a 250-ft. radio telescope—The Director, Nuffield Radio-Astronomy Laboratories, Jodrell Bank, near Macclesfield, Cheshire (October 10).

RESEARCH FELLOW (Ph.D. standard in chemistry or physics and with a sound knowledge of electronics), and a RESEARCH STUDENT (to read for a higher degree in chemistry), for research on new developments of nuclear magnetic resonance spectroscopy—The Secretary, Department of Chemistry, King's College, Strand, London, W.C.2.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

RESOURCES FOR ATOMIC ENERGY AND SPACE RESEARCH

THE subject of space research has already been discussed three times in the House of Commons during the past two sessions: on a motion by Mr. G. de Freitas in April 1959; on one by Mr. F. V. Corfield last February; and on a motion by Mr. G. de Freitas again on July 29. Between the second and third debates, on April 24, the Parliamentary and Scientific Committee was addressed by Sir Edward Bullard, Prof. W. R. Hawthorne, Sir Robert Cockburn and Dr. D. Taylor, and the question of space research was discussed with particular reference to the national benefits that could be expected to accrue from it. The Government's decision to discontinue *Blue Streak* as a military weapon has kept public, as well as scientific, interest in Britain focused on the subject, but in the meantime the announcement that the nuclear power programme is to be retarded has emphasized the comparative limitations of Britain's scientific and technological resources, and the critical character of decisions regarding the allocation of those resources as between one field and another.

There is, in fact, reason for believing that the proposals for space research are now much more realistic, and less likely to distort the general balance of effort in scientific and technological research. Lord Hailsham should be assured of strong and authoritative support in resisting any unrealistic proposals, and the Parliamentary debates and discussions on space research are, in fact, appropriately considered against the background revealed in the White Paper on the nuclear power programme published in June*. It might be noted that the retardation therein outlined was not foreshadowed in the usual White Paper on Capital Investment in the Coal, Electricity and Gas Industries† published two months earlier.

This earlier White Paper put the estimated capital expenditure by the electricity supply industry in England and Wales during 1958–60 at £308·2 million, of which £120·5 million was for conventional and £58·0 million for nuclear stations, compared with £275·4 million, £107·5 million and £46·0 million, respectively, approved for 1960–61; in addition, £6·4 million was spent on nuclear fuel in 1959–60 and £9·6 million is expected to be spent in 1960–61. Most of the expenditure on nuclear power stations in 1959–60 represented progress payments on main constructional works at the first four stations in the programme, and the White Paper notes that payments still to be made for those stations are likely to fall due earlier than had been estimated previously: increased expenditure under these contracts in 1960–61 will be offset by reductions in later years.

The White Paper on the nuclear power programme states that five nuclear power stations are being built and two more have been approved under the programme; the earlier stations will come into operation in 1961 and all seven should be in operation by 1966, with a total output capacity of about 3,000 megawatts. To reach the capacity of 5,000–6,000 MW. by the end of 1966, adopted in 1957 as the basis of the revised programme, exceptionally large orders for nuclear capacity would have to be placed during the next two years for commissioning in 1965 and 1966, and in the meantime the need on the grounds of fuel supply for a sharp and immediate acceleration in the rate of ordering capacity has passed. Accordingly, in consultation with the Atomic Energy Authority, the English and Scottish Electricity Authorities have re-examined the programme with the Government, in the light also of the latest estimates of nuclear and conventional costs and the future availability of primary fuels.

Although the cost of electricity from the first nuclear power stations to be commissioned next year will be rather higher than earlier estimates, the costs of later stations are following closely the downward trend foreseen in 1957, and while, for stations designed to-day, conventional power costs are about 25 per cent less than nuclear costs in the United Kingdom, the Government is advised that, in spite of the unexpected fall in the costs of conventional power from new stations, nuclear generation for base-load purposes is likely to become cheaper than conventional generation by about 1970. While there is a present world surplus of coal and oil, in the long run we shall need increasing supplies of nuclear power, and to secure this we must continue to build nuclear stations on an adequate scale.

The White Paper records the Government's decision to continue for the time being to place orders for nuclear stations at the rate of roughly one every year; and as the capacity of individual stations is likely to increase, this should provide about 5,000 MW. of capacity in 1968. Compared with the 1957 programme and allowing for more conventional stations, this will reduce by some £90 million the cost of power stations to be commissioned during the next seven years and there will be some loss to the Atomic Energy Authority. At any time there should be five or six stations in various stages of development, and it is claimed that this proposed rate of ordering should maintain fully the rate of development of nuclear technology in Britain and sustain a nuclear plant industry capable of competing for overseas business and of expanding to meet the higher level of the future needs of Britain itself.

The Minister of Power was closely questioned about the revised programme in the House of Commons on June 27; but he added nothing substantial to what was contained in the White Paper, apart from stating that for calculating depreciation the life of nuclear power stations was taken as twenty years, though it might be longer, and when they reached the end of their useful lives they would be dismantled, except the reactors, which would be sealed up, and new stations might be built on the same site. On July 28, replying for the Minister for Science, Sir David Eccles said that the slowing down of the nuclear power programme would result in the Authority carrying large stocks of uranium, and it was estimated that the annual interest on the capital locked up in the additional stocks might amount to several million pounds: present estimates suggest that the Authority's current and prospective supplies of uranium would last about ten years. Apart from this, it seems sensible to defer part of the programme rather than run the risk of erecting costly and uneconomic power stations, though there must be some question whether the retarding of construction may hinder the development of more efficient types of reactor.

---

* Ministry of Power. The Nuclear Power Programme. Pp. 4. (Cmnd. 1083.) (London: H.M. Stationery Office, 1960.) 4*d.* net.

† Ministry of Power. Capital Investment in the Coal, Electricity and Gas Industries. Pp. 4. (Cmnd. 993.) (London: H.M. Stationery Office, 1960.) 6*d.* net.

Sir Christopher Hinton scarcely seems to support this view. Discussing, in one of the Royal Society tercentenary lectures (see p. 1064 of this issue), the technical problems which must be solved to reduce the cost of nuclear power to an economically competitive level, Sir Christopher noted that at present the cost of electricity produced by nuclear power plants is 25 per cent higher than that produced by conventional coal- or oil-fired power plants, but that it is expected to drop below that of conventional power before 1970. He then suggested that it would be interesting to speculate on the cost of conventional power generation if it attracted as much research and development as its nuclear rival.

Here, of course, Sir Christopher touched on the essential difficulty that confronts anyone who carries the responsibility for allocating Britain's precious resources of scientific and technological man-power; and Mr. Aubrey Jones, the former Minister of Supply, has even implied that this is the essential reason for establishing a Ministry for Science. As he sees it, the main task of the Minister for Science should be to find a substitute for the technological role which armaments have hitherto played in a free society, with all that that implies in the allocation of resources, the stimulation of research and the fashioning of appropriate relations between industry and government. Mr. Aubrey Jones maintains further that the Minister must operate primarily on the side of demand, that he must seek ideas from industry, and avoid the dispersal of resources, concentrating them on a few major problems, and in particular he urged that the Department of Scientific and Industrial Research and the National Research Development Corporation should be brought into a closer relation and under the same authority—that of the Minister for Science.

The importance of a reasonable balance in the distribution of the resources of Britain is enhanced rather than otherwise by the interaction of different technologies which may be involved in such a field as that of nuclear power, to which Sir Christopher Hinton also alluded in the lecture already noted. Sir Christopher had emphasized that the heat-cycle temperatures in nuclear power plants are lower than the steam temperatures in conventional plants because of the combined effect of the inherent design of a nuclear reactor and the difficulty of finding materials which can stand up to irradiation. If comparable temperatures could be reached in a nuclear plant, Sir Christopher said that nuclear power would already be cheaper than conventional power. Here lie the major problems facing nuclear scientists and engineers at present, and little further advance can be expected, he said, until a new canning material is used for the fuel elements.

The annual reports of the Atomic Energy Authority have frequently indicated the benefits which other technologies have drawn from Britain's programme in nuclear energy, though those benefits are of themselves no justification for disproportionate expenditure of energy in any one field, and they are reasons for some information being published as to the expenditure on research and development by the Authority rather than otherwise. The essential lesson is the imperative need for effective co-ordination, in research and development generally as in fuel and power policy; and if either the Minister for Science or the Minister of Power lacks the authority or resources to formulate and execute such policies, he should not hesitate to approach Parliament for the necessary powers. That undoubtedly is a priority if Britain is to embark in space research on any considerable scale, and in the debate on July 29 Vice-Admiral J. H. Hallett very rightly stressed the need to re-examine the methods by which development contracts of the magnitude required in such programmes are co-ordinated and financed.

Although there are obviously still large problems of administration in research and development which demand some fresh thinking by the Minister for Science, it is no less important that we should be clear before embarking on any large programme of space research as to exactly what benefits the country may derive from such an effort. It is one thing to support projects such as those for which the Department of Scientific and Industrial Research announced last July the allocation of £184,540 to sixteen research groups in British universities for the development of instruments in rockets and satellites; it is quite another to contemplate a programme of space research demanding financial support on a scale comparable with that given to the rest of science. As Prof. Fred Hoyle has emphasized, space research is only a fragment of astronomy, and astronomy itself is only a fragment of science.

In opening the debate on July 29, Mr. G. de Freitas put national prestige as the chief argument for space research and development; but it is difficult to take this argument too seriously. Prof. Hoyle has also questioned whether we are likely to lose any able young scientists even if we do not embark on a space research programme. The really important question is that discussed before the Parliamentary and Scientific Committee and, directly connected with the expected benefits from such a programme, namely, what is a reasonable level of effort in this field. On the scientific side, Sir Edward Bullard referred to the importance of a better knowledge of the high atmosphere for the transmission of radio-waves, to the new opportunities space research offers for investigation of the charged particles in space and for astronomical observations outside the atmosphere. The present programme, he said, is costing about £100,000–£150,000 a year, and he thought this might rise to about £200,000, which is the same order of magnitude as the Department of Scientific and Industrial Research's grant to universities outside nuclear science.

Prof. W. R. Hawthorne, however, urged a programme involving expenditure of £100 to £200 million over the next ten years on launching space satellites and probes, and justified his claim on the ground of advances anticipated in control devices, communications and power, as well as in structures and mechanical engineering. He thought, for example, that the impetus given by the jet engine to research and development in combustion was likely to be repeated as engineers tackled the problems of rocket combustion, and similarly in connexion with the transmitters and receivers designed for space research to detect weak signals in a background of noise would be invaluable to industry in the next decade. Beyond this, however, Prof. Hawthorne argued that failure to support a serious space project would reduce the number of innovations we develop, innovations which might be of material advantage to industry as a whole, and it would also reduce the resources of skill and experience on which our designers could draw. Innovation, he insisted, is a product of imagination, skill and chance, and without entering on any discussion of the relation between discovery and innovation, he strongly urged the importance of an environment which fosters innovation, such as a space project should provide, in the education of the engineer.

Sir Robert Cockburn said that, of possible applications of satellites, only their use for long-range communications, in reconnaissance and in navigation could yet be considered in detail, and Dr. Denis Taylor stressed more particularly the stimulus space research could bring to instrumentation and to continental telephone and radio communication. In the discussion, Mr. A. Albu questioned whether engineering and scientific achievements could not be maintained more cheaply by spending money in some of the industries. Prof. Hawthorne admitted that it is difficult to explain the working of the intellectual stimulus and, as he also said, the Department of Scientific and Industrial Research had long been seeking to introduce science into British industry, but with only partial success. He agreed with Lord Halsbury as to the need for understanding why industrial design teams and others behave as they do, and the discussion certainly focused attention on the critical importance to Britain of such understanding for the proper deployment of our limited scientific resources.

Something of this discussion was reflected in the debate in the House of Commons on July 29. Mr. de Freitas, asserting that for speech, and later for television, satellites offered a far greater capacity and economy than ordinary terrestrial radio or cables, quoted opinion from the telecommunications industry that while for the first three years a telephone call to Australia might cost £1 a min., within four years a profit would be made at 10*s*. a min., and within twenty years anywhere in the world could be reached at 6*d*. a min. and be highly profitable. It is estimated that this could be achieved for an outlay of £6 million in the first year and a total of £80 million over forty years, and the system should have an income of £3·7 million in the first year, rising to more than £50 million in twenty years.

Mr. de Freitas also referred to the use of these satellites, for navigation and weather forecasting; but while, in replying on the debate, the Parliamentary Secretary to the Ministry of Aviation, Mr. A. G. E. Rippon, agreed that great scientific, technological and commercial benefits might be expected to result from space research, he pointed out that scientists themselves are divided on the question, and he again stressed the importance of considering the possibilities of international co-operation in this field. The debate had concentrated on the question of the development of *Blue Streak* as a satellite launcher, but on this Mr. Rippon had nothing to add to what the Minister of Aviation, Mr. Duncan Sandys, had told the House on June 20. Mr. Sandys said then that he was keenly aware of the potentialities of a British space research programme, but that he was not yet in a position to announce any decision. He also said that the French and German Governments appeared to be considerably interested in the idea of co-operation, but that before taking any decision the Government would consult the Australian Government.

Mr. de Freitas did not repeat what he had said in replying on the debate on February 22 about the British contribution to various space research programmes. Since the decision to abandon *Blue Streak* as a military weapon was announced, work had continued on those parts of the project which are necessary to its adaptation as a space satellite launcher and there was no evidence to show that these important design teams were splitting up, though he appreciated that excessive delay in reaching a decision could have adverse effects. Meanwhile, work on the technical problems associated with a future space programme had confirmed that a launcher could be developed from our abandoned military project capable of putting into orbit an array of satellites, and the design studies indicated that at least three types of satellite could be launched.

Although Mr. Rippon did not go into details of the scientific programme which could thus be carried out, his references to telecommunications, meteorology and to the stimulus of new technology and innovation suggested that the Government has already been considerably impressed by what was said before the Parliamentary and Scientific Committee, the memorandum from the British Interplanetary Society and other representations. Equally it would appear that the Government is concerned to maintain the balance of the research effort of Britain and avoid the distortion which Prof. Hoyle and others fear. Some scientists like Sir William Slater and Dame Kathleen Lonsdale fear that space research will divert skilled man-power from more important fields of research; but while Sir Frederick Brundrett suggests that a programme of space research should normally run with a military programme for the development of liquid-fuelled rockets and thus, like Prof. Hoyle, appears to question whether the successful development of a satellite relay system really lies within the range of a *Black Knight–Blue Streak* programme, Prof. Hoyle seems to be alone in doubting whether sufficient sound ideas for space research have yet been advanced to prevent the decline in standards which tends to result if too much money chases too few ideas.

There seems little reason to doubt that the Advisory Council on Scientific Policy took the right line in its annual report for 1958–59, from which Mr. Rippon quoted in the debate on February 22. British science and technology have contributed, and will continue to contribute, valuable results in space research, but these contributions should be made in specific directions appropriate to our special skills and they should be part of an internationally based approach. There does not indeed appear to be any reason on financial grounds or those of scientific and technical man-power why Britain should not afford such a programme; but a sound decision will be reached much more readily when the results of the design-studies recommended by the Advisory Council are available.

Meanwhile, the importance of a close assessment of the distribution of Britain's effort in research and development, including that of the universities as well as of Government and industry, is obvious, and this should be receiving the urgent attention of the Minister for Science. Moreover, it should not be forgotten that while Mr. Rippon rightly stressed the need to consider carefully all possibilities of international co-operation in space research, a report last March by Mr. D. Wilgress on co-operation in the field of scientific and technical research to the Organization for European Economic Co-operation strongly urged the need for more co-operation, particularly in fundamental research. Still more recently, industrial leaders like Viscount Chandos and Dr. Solvay have urged the need for more co-operation in fundamental research within particular industries, again on the ground of avoiding waste of limited resources, and especially of trained man-power. The Government is right in refusing to be rushed into any hasty or premature decision as to entering or not on a programme of space research; but it is for the Minister for Science to make sure that all the relevant factors are taken into account, including the interaction of different technologies on one another and the functioning of innovation and invention. Not all these factors can, it is true, be estimated with any accuracy; and there is sound reason for putting some further studies in hand. If the results will not be available in time to guide the decision regarding space research, they should assist similar decisions which are bound to recur from time to time in an age of advancing technology.

SEMICONDUCTORS AND TRANSISTORS

Les Semiconducteurs

Par Prof. P. Aigrain et F. Englert. (Monographies Dunod.) Pp. x+203. (Paris: Dunod, 1958.) 980 francs.

Les Semiconducteurs Électroniques

Introduction à la Physique des Redresseurs et des Transistors. Par Dr. E. Spenke. Traduit par L. Godefroy. Pp. xx+349. (Paris: Dunod, 1959.) 5,600 francs.

The Properties, Physics, and Design of Semiconductor Devices

The Junction Transistor and its Applications

Edited by E. Wolfendale. Pp. viii+394. (London: Heywood and Co., Ltd., 1958.) 84*s*. net.

THE subject of semiconductors was understandably not popular with authors of books during the period when the two semiconductors in common use, copper oxide and selenium, and rectifying contacts made to them, were proving such severe tests of the theories of the solid state then being developed. Industry found it necessary to use empirical methods to improve these materials for use in rectifiers, thereby, as it happened, tending to increase the difficulty of closing the gap between theory and practice.

The whole outlook of the subject was ultimately changed, not by the resolution of the difficulties which made the subject so obscure, but by rapid advances following comparable observations of materials more amenable to scientific investigation. Germanium in particular proved to be a semiconductor well suited to study by physicists; the discovery of transistor action and its explanation in terms of minority carriers acted as a great new stimulus, and the refinements made to the methods of preparing germanium, and later silicon, with very small, but controlled, amounts of desirable impurities quickly increased confidence in quantitative measurements. New electrical properties of semiconductors were discovered and fitted into the expanded theory, and its adequate explanation of the behaviour of p-n junctions was one of its greatest successes. To-day therefore, despite some difficulties which the subject has run into in its newer fields and in some details, the basis of the subject is well established and the problems facing authors of books on the subject are an over-abundance of original and review papers and the rapidity of advance. In addition, the readers have changed; few continue to regard the subject as a test of the powers of quantum mechanics, for it has had important reactions on the basic theories and is big enough to demand specialized treatment. Most readers will be content if the specialized treatment is only sufficiently rigorous to contain the more important basic physical effects, and will expect a compact picture of the positive achievements and applications of the subject which has spread into several branches of science.

Prof. Aigrain and his co-author make little concession to these readers in so far as they assume that a study of quantum mechanics will already have been made—even if many details have been forgotten—and that frequent recourse to fundamentals is essential. They begin with a highly condensed account of the role of electrons in solids, largely in mathematical terms and divorced from physical quantities directly observable, into which they then fit a few practical findings. The bare outlines of the properties of junctions and transistors follow, expressions still being quoted rather than deduced, and the book ends on a lower intellectual note, with summaries of the preparation of transistor-quality germanium and silicon and of some photoelectric and thermo-electric applications. The merits of this short book as a summary of the formal theory for those readers already well acquainted with the subject are likely to be its greatest demerits for others.

The second edition of Spenke's book was translated into English last year by staff of the Radio Corporation of America, who made some useful additions; the French translation, which seems a little less free by comparison, includes the addition describing junction capacitance. The book is in two overlapping parts. The first four chapters form one part and take us from band theory to the physical mechanisms of transistors; mathematics and wave-mechanical ideas take second place to descriptive language, but the author avoids over-simplification. The second part is intended for the physicist who requires a more comprehensive analysis of the physical processes responsible for the properties of semiconductors. It reveals the more successful work of the period 1930–40, made despite the difficulty of experimental confirmation, though it may over-emphasize some at the expense of more recent findings.

Shive, too, though writing for readers with little prior knowledge, divides his book into two distinct parts. The first, once again, is very descriptive, both of semiconductors and of the chief devices made from them—thermistors, point-contact diodes, rectifiers using copper oxide and selenium, photocells and junction transistors. A scientist in a non-physical field could benefit equally with any newcomer. The second part begins by inquiring more deeply into the physics of semiconductors, largely in terms of particle models, with occasional reference to wave and quantum mechanics; some over-simplifications may have crept in, but the chief points are well put. The key points of junction theory are presented without frills, and the book concludes with chapters on thermoelectricity, the Hall effect and the processes used to make junctions. The whole is worth study by those who teach the subject as well as by those seeking a broad understanding which is, however, more than superficial.

Despite the fair number of books on transistors now available, it is still difficult to say how best the subject can be presented, either for beginners or for experienced designers of devices and circuits. If reasons are to be given for the electrical properties, some recourse to physics is necessary; but if they are not, a statement of the properties and their translation into analytic form can prove an adequate starting point for a book on applications. Gillie's attempt, aimed at a non-analytic introduction to the device and its elementary circuits, is not badly planned, but must be very nearly completely discounted because of the numerous errors and misleading statements early on. Thus he talks of the velocity of current, confuses resistance and resistivity, asserts, with the emphasis of italics, that pure germanium is an insulator, seems to imply that acceptors increase the conductivity of a semiconductor, because the electrons from the valence band filling the acceptor-levels then require less energy to be excited to the conduction band and states that hole-electron pairs can be more easily created in n-type material. The two chapters on the junction transistor can be recommended to the newcomer without serious reservation, provided he has other sources to refer to at the same time.

On the other hand, Wolfendale and the contributors to his book have produced something worth the serious attention of electronic engineers. The opening chapter, of some length, on transistor physics is specially noteworthy, for, from a simple beginning, it develops analytically all the main electrical properties of the uniform-base transistor; an extension to graded-base units would be valuable in any second edition. Several of the later chapters are of the standard expected in a good designers' hand-book, and all have some merit. Continuity is sometimes a little lacking, and some parts are treated in much more detail than others; but there are no inconsistencies and few misleading statements. The book was written before the idea was advanced that the charges stored in the base and in depletion layers furnished a basis for predicting the behaviour of transistors as switching elements; but it does illustrate the difficulties of finding a single representation for a transistor adequate for all applications.

J. R. TILLMAN

COMMUNICATIONS AND ELECTRONICS DICTIONARIES

Elsevier's Telecommunication Dictionary in Six Languages

English/American—French—Spanish—Italian—German—Dutch. Compiled and arranged on an English Alphabetical Base by A. Visser. Pp. viii+1011. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1960.) 147*s*.

Swedish Supplement to Elsevier's Dictionary of Electronics and Waveguides

By W. E. Clason. Pp. iv+43. (Amsterdam: Elsevier Publishing Company; London: D. Van Nostrand Company, Ltd., 1960.) 20*s*.

THE first volume is a very welcome addition to the series of multilingual dictionaries published by the Elsevier organization. Its compilation is more than justified by the enormous progress that has taken place in the field of communications, both line and radio, in the past one or two decades. This volume has been compiled by Mr. A. Visser, who retired a few years ago from the position of librarian and chief of the documentation section of the Netherlands Postal and Telecommunication Services. The basis of the book is the listing of all terms used in the telecommunication world arranged in alphabetical order in the English language. Below each term is given the equivalent word or phrase in French, Spanish, Italian, Dutch and German in that order. In many cases it has been necessary to give alternative words or phrases in interpretation of the basic English term or phrase. No definitions of the terms are given, but, in a large proportion of cases, the terms are sufficiently self-explanatory for the technical reader.

Following the basic section, alphabetical lists are given in each of the other five languages, each word being indexed as a reference to the basic table, so that the user can find the corresponding term in English, and all the equivalents in the other languages.

As with former volumes in this series, the production of the book is excellent. In spite of its size—more than one thousand pages—it is convenient to use, with the familiar semi-flexible binding, and a thumb-index to the different languages. All engineers and scientists engaged in the field of telecommunications will find this a most useful work of reference and aid to the reading of foreign literature.

A dictionary on similar lines to that referred to above but dealing with the field of electronics and waveguides was published by the same company in 1957 (see *Nature*, 181, 801; 1958). To the language section of that volume has now been added a Swedish supplement. This is arranged in two parts: the first being an alphabetical list of terms in this language; while the second comprises a re-arrangement of the same terms in the numerical order corresponding to the numbered basic English section of the main dictionary. The publication of this supplement thus extends the former volume to be a complete work of reference in seven languages to all terms in use in the technique of electronics and waveguides.

R. L. Smith-Rose

PROBABILITY AND PHYSICS

Probability and Related Topics in Physical Sciences
By Mark Kac. With special lectures by G. E. Uhlenbeck, A. R. Hibbs and Balth. van der Pol. (Lectures in Applied Mathematics, Vol. 1.) Pp. xiii+266. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959.) 43*s*.

THIS book, which is based on a course of lectures given in 1957, makes no claims to be a text-book; but it contains a wealth of material underlining the established place of probability technique in modern physics. Prof. Kac's enviable skill in analysis is somewhat naturally displayed to the full in many of the problems discussed, so that, while the mathematics always remain his servant, his book may in consequence appeal rather more to mathematicians than to physicists.

There are four chapters and four appendixes. Chapter I explains the nature of probabilistic reasoning, and includes discussion of the Maxwell velocity distribution in the theory of ideal gases and of the number of real roots in polynomial equations with random coefficients. Chapter 2 deals with "Some Tools and Techniques of Probability Theory", illustrated mainly by reference to various random walk problems. The longest chapter (3) is on "Probability in Classical Statistical Mechanics", and the first appendix by G. E. Uhlenbeck on 'the Boltzmann equation' should be read together with this chapter. Uhlenbeck's appendix gives a very clear survey of the various models, microscopic and macroscopic, mechanical (deterministic) and stochastic, that exist and the relations between them. In Chapter 3 itself, the fundamental problems and paradoxes of statistical mechanics are considered by reference to the Ehrenfest urn example, by the use of the so-called 'master equation' which represents a stochastic simplification of the exact Boltzmann equation, and by a modern account of Smoluchowski's brilliant theory of fluctuations.

The final chapter (4) is on "Integration in Function Spaces and Some Applications", and discusses the recent technique of path integrals introduced into quantum mechanics by Feynman and having analogues in the theory of stochastic processes. There is a relevant appendix (2) on quantum mechanics by A. R. Hibbs, recalling some of the special peculiarities of probability in this domain. The final appendixes (3 and 4) by B. van der Pol, on "Smoothing and Unsmoothing", and "The Finite Difference Analogy of the Periodic Wave-equation" and the "Potential Equation" respectively, are not directly related to the rest of the volume, which ends with some interesting historical notes and a bibliography.

One important topic omitted from this book is information theory; this might be explained by Prof. Kac's concentration on problems closely connected with his own researches. It might also be argued that this theory is more related to communication engineering than to physics: but more fundamentally its bearing on the concept of entropy and on theories of measurement has yet to be fully clarified. On the subject-matter of Chapter 4, the mathematical connexion between the Feynman integral and analogous integrals in stochastic process theory is stated clearly enough, but on a deeper physical level the differences seem puzzling and remain rather a challenge. I was also somewhat surprised not to find a more explicit discussion of the important class of probability problems associated with such work as Onsager's on the two-dimensional Ising model, to which a very fleeting allusion is made in the bibliography (p. 261). However, even this last comment can scarcely be a criticism of the book under review, when it is recalled that the author's intention was to indicate the scope and value of probability theory, and part, but by no means all, of its rapidly increasing range in physics.

M. S. Bartlett

ADVANCES IN GEOPHYSICS

Advances in Geophysics
Edited by H. E. Landsberg and J. Van Mieghem. Vol. 4: Pp. x+456. 12 dollars; 86*s*. Vol. 5: Pp. x+325. 10 dollars; 80*s*. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1958.)

IN these volumes, as in past issues, geophysics is interpreted in the widest sense with perhaps a greater emphasis on pure geophysics than prospecting geophysics. If it is the editorial policy that the subjects selected for review reflect the state of research among the Earth sciences, it would appear that meteorology and upper atmosphere physics lead the field, for almost half the articles in the volumes under review concern these subjects. The International Geophysical Year stimulated research in all branches of geophysics as Gerson's article "Polar Years to I.G.Y." (Volume 5) illustrates, and it is to be hoped that future issues of "Advances in Geophysics" will take account of this activity, particularly in the fields of geomagnetism and seismology.

In reviewing the organization and achievements of the First Polar Year, Second Polar Year and the International Geophysical Year, Gerson remarks on the accumulation of "mountains of undigested data". The institution of world data centres by the organizers of the International Geophysical Year to co-ordinate and standardize the accumulated data makes it all the more imperative that geophysicists should be trained in computer programming methods in order to assimilate this data. Any student in this field is well advised to read Holloway's review on "Smoothing and Filtering of Time Series and Space Fields" (Volume 4).

Hirvonen, in "The Size and Shape of the Earth" (Volume 5), describes recent advances in geodetic surveying and also discusses the application of Stokes's formula to determining the geoid. Those minute oscillations of the Earth's crust due to Earth tides are reviewed by Melchior in "Earth Tides" (Volume 4). The remarkable sensitivity of the horizontal pendulums, extensometers and gravity meters (which the author describes) is exemplified in the attempt during the International Geophysical Year to detect the change in Love's numbers with tidal periods attributed to motions in the fluid core. While Earth tides can be dealt with largely by static theory, ocean tides demand a dynamic theory. The theoretical and empirical study of tides in uniform and actual oceans is reviewed in Volume 5 by Doodson.

On microseisms, the late B. Gutenberg (Volume 5) emphasizes the difficulties inherent in a branch of seismology which deals with dispersed sources involving energy transfer from wind–water–Earth and propagation by surface and channel waves.

Junge, in "Atmospheric Chemistry" (Volume 4), reviews recent research on aerosols and trace gases. Among other trace gases the role of carbon dioxide in the heat budget of the Earth is discussed. In "The Physics of Cloud Modification", Volume 5, the entire history of cloud-seeding techniques is outlined by MacDonald together with a discussion on condensation and precipitation processes in clouds.

Further afield, Watanabe (Volume 5) gives an extensive account of ultra-violet absorption cross-sections and absorption processes in the ionized regions. Rocket and satellite studies have also contributed to the revolution now taking place in theories of magnetic storms which have a direct bearing on theories of the aurora. Chamberlain (Volume 4) reviews these theories, discussing at length the Chapman–Ferraro theory of storms since this remains the most rigorous treatment that takes account of auroræ.

Lapaz (Volume 4) provides the first extensive account of "The Effects of Meteorites upon the Earth" discussing not merely the composition, trajectories, etc., of meteorites but also the probability of their striking densely populated areas.

These two books maintain the high standards of previous issues and deserve a place on most geophysicists' bookshelves.

S. H. HALL

BIOLOGY OF POLLUTION

The Effects of Pollution on Living Material

Edited by W. B. Yapp. (Symposia of the Institute of Biology, No. 8.) Pp. xii+154. (London: The Institute of Biology, 1959.) 25s.

The Biology of Polluted Waters

By H. B. N. Hynes. Pp. xiv+202+2 plates. (Liverpool: Liverpool University Press, 1960.) 25s. net.

The Church Army Press is perhaps partly to blame for the style of the Eighth Symposium of the Institute of Biology "The Effects of Pollution on Living Material". Although expensive the quality of production, paper and printing is poor and while this may have been specific to my copy the contents must be general. After two good introductory contributions the symposium lapses into a stage for mere repertory and is saved only by the last chapters on pollution, in its widest sense, by radioactive materials. Although at present mostly fall-out, some contribution to radioactive pollution is made by nuclear power stations and general radioactive waste disposal from hospitals and industry for which there is still no national scheme. With radioactive pollution at its present level, such effects as an eventual increase of 5,300 in the number of blind persons in Great Britain may be expected. It seems, however, that, except for tritium and carbon-14, both soft beta emitters, cobalt-60 with a half-life of 5 years is the longest-lived nuclide in fall-out. Improvement would therefore be quite rapid if bomb testing was to stop.

While the chemist interested in water has for a long while been well equipped with books on pollution, biologists have hitherto had probably only one recent book, namely "Aspects of River Pollution" by Dr. L. Klein, to draw upon. That work is primarily a reference book, while "The Biology of Polluted Waters", by Dr. Hynes, in which frequent reference is made to Dr. Klein's book, provides for the first time an introductory text for any biologist sufficiently interested in pollution to be intrigued by the striking cover. In the preface and throughout the book Dr. Hynes emphasizes the essentially biological nature of pollution and the incongruity of the older chemical approach. Mr. F. T. K. Pentelow too, who wrote the introduction, criticized some of the river boards for expecting the chemists on their staffs to understand and tackle alone problems so essentially biological.

Having experienced the difficulty of communication with chemists who are often unfamiliar with biological concepts, the author has provided a kind of picture vocabulary to help the non-biologist reader, but it is doubtful whether this simple device will in fact bridge the gap between the worlds of the chemist and the biologist.

To most people pollution has a definite connotation; but perfectly natural phenomena, such as the autumn fall of leaves or a sudden summer shower, may deplete the dissolved oxygen in a river enough to be catastrophic for the inhabitants. Similarly, pollution of lakes may merely hasten the natural hydrosere from oligotrophic to eutrophic condition. Where then is the border-line between natural and polluted water? Only complete understanding of the biology of a whole waterway can justly answer this question in any particular case, yet, as the author points out, still too little is known for this often to be possible. Perhaps the best basis for a general judgment on the condition of a river is given by Turing cited by Hynes. "Fish are a very useful barometer of the real state of purity of a water. No river should be considered as in a satisfactory condition unless fish will live and thrive in it".

In short, the book sums up the work of the Water Pollution Research Laboratory, the Freshwater Biological Association and authorities in Europe and the United States, in a comprehensive and above all eminently readable way. G. C. WARE

NORTH AFRICAN PREHISTORY

The Stone Age in Northern Africa

By C. B. M. McBurney. (Pelican Book No. A342.) Pp. 288+24 plates. (Harmondsworth, Mddx.: Penguin Books, Ltd., 1960.) 6*s*.

DR. McBURNEY is among the half-dozen prehistorians who are really competent to write about the early prehistory of North Africa. Over a series of years he has visited much of the area and has himself made there important excavations. His book, therefore, can be confidently recommended to all students of the subject.

As a lecturer and teacher in the University of Cambridge who has travelled widely, he brings to bear on the problems of North Africa a wide knowledge of prehistory elsewhere, and seeks to fit his special area into the pattern of the Stone Age world. Thus he begins his book with 60 pages on "The Present Stage of Prehistoric Studies"—a chapter which will be appreciated both by his less- and more-instructed readers, and which presents the problem of North Africa in relation to the neighbouring areas of Europe, western Asia and Africa south of the Sahara. He then discusses the physical and climatic problems of his own region. Climatic changes in the past have profoundly affected the possibility of habitation during prehistoric times. Prior to the last pluvial period (Gamblian) the spine of the Sahara could be traversed from south to north, but afterwards such movements were, to say the least, difficult on account of the absolute desert conditions which set in.

Next come three chapters which perhaps are the meat of the book and which deal, in order, with "The Earliest times of Man in North Africa", "The Middle Palæolithic" and "The Blade Industries and the Spread of *Homo sapiens*". In the first of these it is splendid to be given, with proper recognition of its importance, an account of the work of Arambourg and his finds of early Acheulean human remains at Ternifine (Palikao). To English readers such an account has not hitherto been readily available. Villafranchian faunal assemblages used as date-giving fossils are discussed and there are comparative faunal tables and some, perhaps not enough, text figures of varying excellence of some of the implements found. In the Middle Palæolithic chapter the author has much excavated material to discuss and many problems, and can draw on the work of Miss Caton Thompson again and again. There is a charming account of his own finding of a hunter's encampment site near the Wadi Derna in Cyrenaica, with a list of the animals eaten there, and where the typology of the finds brings to mind the industrial tradition of the lower Levalloiso-Mousterian of Palestine. In the "Blade Industries" chapter his own excavations have again helped the writer. The problems are more than ever complicated as he admits, but as a working hypothesis he offers a series of dates starting at 15,000 B.C. with the appearance of the earliest Oranian in the Maghreb as a result of Gravettian influence or immigration from south-west Europe into a Levalloisean area until 5000 B.C., when the Upper Capsian seems to come to the end of its sway and Levantine influences are apparent. A final chapter on the Neolithic period, which gives a picture of a surprisingly uniform cattle-breeding (but sheepless and goatless) economy extending from the Atlantic to the Nile, includes a short account of less than 15 pages of the North African rock-shelter art and about the same number of pages of illustrations, principally, I fancy, taken from Frobenius. On this matter, of course, a great deal more could be written, but the survey will be found useful to students. It is in a connexion like this that one must regret that owing to the economic problems of to-day such a fundamental study as this book could not have appeared in a larger format. So much which the author has touched on could have been usefully expanded. Nevertheless we now have, together with the complementary volumes in the series by Desmond Clark and Sonia Cole, three authoritative works on the prehistory of the continent of Africa.

M. C. BURKITT

EXISTENTIAL PSYCHIATRY

The Divided Self

A Study of Sanity and Madness. By Dr. R. D. Laing. Pp. 240. (London: Tavistock Publications, 1960.) 25*s*. net.

THIS book will be of interest to those who are orientated towards philosophy, but others may find it difficult going. The author is obviously widely read in existential and other modern philosophical theories and has attempted to apply them to understanding psychiatry—particularly schizoid personalities and schizophrenia.

The main weakness of the book is that it does not develop a coherent system, but uses the existential ideas to explain some patients' symptoms without giving a satisfactory scheme which is applicable in other cases. In some instances he sets up 'Aunt Sallies' only to knock them over. For example, he complains that "the current technical vocabulary currently used splits up man verbally". By this presumably he means that one speaks of the ego, super-ego and id and so on. Yet this does not split up man verbally unless one regards an engineer who talks of the cylinder, piston, connecting rod and crank-shaft as splitting up an engine verbally. They are merely descriptive terms, and he still regards it as a whole engine.

The author puts forward a number of interesting mechanisms in schizophrenia, for example, engulfment, implosion, petrification, and depersonalization. He believes that the 'inner self' undergoes various changes in this disease and can be 'phantasicized' or 'volatilized'; it can become unreal, or impoverished, empty, dead, or split; it can be more and more charged with hatred, fear and envy.

The author complains that psychiatric theory has not changed since Kraepelin (although Freud changed a good deal), and perhaps he has laid the foundations of a system which he may be able to develop further in other books. CLIFFORD ALLEN

Safety in Mines Research Establishment Bibliography, 1960

Compiled by E. B. Smith. Second edition. Pp. viii+177. (Sheffield: Ministry of Power, Safety in Mines Research Establishment, 1960.) 17*s.* 6*d.*

THE organization known since 1950 as the Safety in Mines Research Establishment of the Ministry of Power has operated in one form or another since 1908. It has made noteworthy contributions to knowledge not only of the immediate problems of safety in mines connected with dusts, ventilation, inflammable gases, explosions, roof control, methods of working, lighting, health of the miner, electrical hazards, materials used in mining, and so forth, but also of fundamental scientific knowledge to a whole wide range of subjects which affect mining and mining conditions. These include physics of liquids and of fine particles, gas flow, ignition and combustion of gases and solids, flame propagation and explosions, metallurgy, coal constitution, palæobotany, medical science, etc.; this list is not exhaustive, but is a selection to show the breadth of interest of the Establishment as a whole. There are, in fact, more than 1,500 entries in this comprehensive bibliography (which supersedes the Safety in Mines Research Establishment Bibliography, 1921–52, and includes publications up to the end of 1959, as well as references to international conference papers translated and published by the Establishment).

The scope of the Establishment is wide because problems of safety in mines touch almost every science and technology. The bibliography, therefore, will be of interest to workers engaged in many fields of pure and applied science. It is well arranged and well presented for its price; but what a pity that it is stapled in such a way that the sharp ends of the staples can scratch—and in the case of one copy already have scratched—the surface of a polished table.

S. G. WARD

South African Animal Life

Results of the Lund University Expedition in 1950–1951, Vol. 6. Edited by Bertil Hanström, Per Brinck and Gustav Rudebeck. Pp. 553. (Stockholm: Almqvist and Wiksell, 1959.) 75 Sw. kr.

A CONTINUATION of what has now become a well-known series, this sixth volume follows the style of its predecessors. Like them, it is particularly pleasant to use because the various type-faces are well-chosen and attractive, and combine to make the text most readable. The crown octavo pages are bound in such a way that the volume stays open without trouble. A consistent editorial policy makes all papers present equivalent information: synonymy; systematic notes; descriptions of new genera and species; detailed and general distribution. The volume as a whole is rather lightly illustrated, though some papers have good figures.

This sixth volume includes accounts of the following groups of animals, as they were represented in the collections made by the Lund University Expedition during 1950–1951: Hirudinea (I. Sciacchitano); Diplopoda, Penicillata (B. Condé); Collembola (J. Paclt); Coleoptera, Scarabaeidae-Hopliini (H. Schein); Bostrychidae (J. M. Vrydagh); Erotylidae (H. Philipp); Endomychidae (H. F. Strohecker); Colydiidae (R. D. Pope); Monommidae (H. Freude); Cerambycidae (F. F. Tippmann); Chrysomelidae I (G. E. Bryant); Chrysomelidae II (J. Bechyné); Curculionidae, part (G. A. K. Marshall); Curculionidae-Brachycerinae (E. Haaf); Neuroptera, Plannipennia II (B. Tjeder); Diptera, Culicidae (J. Muspratt); Ceratopogonidae (B. de Meillon); Mydaidae (M. Bequaert); Stratiomyiidae (E. Lindner); Phoridae (E. M. Beyer); Dorilaidae (Pipunculidae) (D. E. Hardy); Chloropidae (C. W. Sabrosky); Hippoboscidae (J. Bequaert); Streblidae (B. Jobling); Calliphoridae (F. Zumpt); Hymenoptera, Ichneumonidae (P. L. G. Benoit); Gasteruptionidae (J. J. Pasteels); Megalyridae (K. J. Heqvist); Sapygidae (P. L. G. Benoit); Pompylidae (G. Arnold); Amphibia (R. F. Inger).

There is a contents page, but this volume is not separately indexed.

H. OLDROYD

Les Observatoires Astronomiques et les Astronomes

Par Fernand Rigaux. Pp. ii+452. (Bruxelles: Observatoire Royal de Belgique, 1959.) n.p.

THIS is a new edition of a work which appeared originally in 1931 and has been very useful as a reference book. Many astronomers must have regretted frequently that the only supplement was made in 1936, so that the work was no longer of any use. It gives the names of the astronomers in all the principal observatories, and a brief description of the instruments to be found in them, and in addition it gives the addresses of retired observatory astronomers, university professors and lecturers interested in astronomy, and indeed of prominent amateur astronomers.

While the Royal Observatory of Belgium, and Fernand Rigaux in particular, are to be congratulated on the production of a new edition, it is impossible not to regret the fact that the information which now appears is four years out of date, at least so far as several British observatories are concerned that I have checked in detail. One might also suggest that a formidable book of 452 pages is not really necessary to convey the information. It is possible to criticize the lay-out, which seems to be very wasteful of space.

I would be heartily in favour of bringing out this reference book more frequently in a handier and cheaper form.

R. v. d. R. WOOLLEY

The Faith of a Physicist

By Dr. H. E. Huntley. Pp. 159+4 plates. (London: Geoffrey Bles, Ltd., 1960.) 16*s.* net.

IN a foreword to this book, Prof. C. A. Coulson commends it "as an honest attempt to help others to see the present status and future possibilities of science. In its simple and direct style it can hardly fail to instruct and to encourage its readers".

It is desirable that writers with a special knowledge of one branch of science should, on occasion, relate their scientific outlook to their attitude towards the Christian faith. This the author, lately professor of physics in the University College of Ghana, has done. In the first chapter, "The Status of Science", Prof. Huntley maintains that science "is not only more than technology; it is more also than a social force of unprecedented power. *Science is a revelation and its study is a religious activity*". Successive chapters expand this theme in relation to such subjects as education, beauty as revealed in Nature and the stature of man.

A feature of the book is the number of literary quotations which the author uses to illustrate his argument.

H. D. ANTHONY

EVOLUTION OF NUCLEAR POWER PLANT DESIGN*

By SIR CHRISTOPHER HINTON, K.B.E., F.R.S.

MOST applied research is expensive, and applied research and development on atomic energy is so expensive that expenditure should be justified either by the needs of defence or by the expectation of a satisfactory return in the industrial field. The foundations of the atomic energy industry were paid for with defence funds; the research, development and engineering of the fuel-element manufacturing plant at Springfields, the diffusion enrichment plant at Capenhurst and the Windscale reactors and chemical separation plant were done to produce plutonium and uranium-235 for defence. Even the Calder Hall reactors were built primarily for the production of plutonium, and generated electric power as a by-product. The possibility of using this experience in the industrial field had been seen from the first, and progress into this field had been planned. But now that we have advanced into it, little of the further research and development which are necessary can reasonably be charged to a defence budget; they must be justified by immediate or prospective savings as compared with alternative industrial techniques which are available or are likely to be available.

When the British nuclear power programme was first launched in 1955, it was estimated that (in the first stages of development) the cost of nuclear and conventional power would be equal at about 0·6*d.* per unit of electricity. Since then there have been three important changes; because of rapid development in that field, the cost of conventional power has fallen by more than 10 per cent; for technical and commercial reasons the credit allowed for by-product plutonium (which it is hoped to use as fuel in reactors of advanced types) was drastically reduced; interest rates (which had been taken at 4 per cent) have risen, and this rise reacts against nuclear power with its high capital cost. The result of these changes is that nuclear power from the plants which are now being ordered will cost about 25 per cent more than from the best conventional plants built concurrently and operated under similar load conditions.

That a difference of this sort was likely was known at the time when the nuclear programme was expanded in 1957; the expansion was justified by the immediate anxiety about fuel supplies in Britain at that time, by the fact that forecasts then made of fuel available for electricity generation suggested that the ceiling would be reached by 1965, and by the fact that (because the nuclear power industry was new) important reductions in cost could be expected. Since then both the short- and the long-term positions in regard to coal supplies have changed; there is a present surplus of steam coal, not only in Britain but also in many overseas countries; the long-term forecast of supplies of coal for steam-raising suggests that (without a nuclear programme) supplies could meet demand until about 1970. In these changed circumstances the nuclear programme was revised in June 1960, but the reduced programme can only be justified if it gives promise that it will give cheaper power than can be obtained from conventional fuels at a reasonable date in the future. If it gives that promise, as indeed it does, a programme involving the construction of many successive power stations, each of which will be less economical than conventional stations built concurrently, is justified, because research, development and large-scale construction and industrial use must move forward hand in hand; research in such a field is not effective if it moves too far in advance of application.

The cost of power from every form of prime mover has fallen as, with the passage of time, it has been possible to achieve higher top temperatures in the heat-cycle used by that prime mover. When the first industrial reactors were built at Windscale, the heat of fission was wasted because it was not possible to recover it at a high enough temperature. In the Calder Hall reactors the heat was recovered at a temperature just high enough for use; but even in the industrial reactors which are being built to-day, the top temperature of about 380° C. which is being achieved in the steam-cycle is at a level which was common in conventional steam-power plant practice twenty-five years ago. Nuclear power can thus be made cheaper by achieving higher temperatures in the heat-cycle; types of reactor which do not give promise of these high temperatures are only of passing interest or of interest only in specialized fields of application.

But advances in technology bringing down the cost of power generation are still taking place in the conventional field, so that the point at which the cost of nuclear power breaks even with, and then falls below, the cost of conventional power is determined by the convergence of two falling curves of cost. Before we look at the prospects in the nuclear field, it is worth while to examine the trend in conventional power plants.

The downward trend in capital cost of steam-power plants extends back to the earliest days of the steam engine (Fig. 1). The scatter of points on which the curve is based is naturally wide because plants have (at each date) been built of different sizes and for different conditions, but the trend is clear. In this period the top temperature in the steam-cycle has risen from 100° C. to 570° C. or, in some present-day pioneering plants, even higher. It would be wrong to suggest that the continuing fall in capital cost is due only to continued ability to achieve higher top temperatures in the heat-cycle, but the advance to higher temperatures is the backbone of the development. The use of higher top temperatures was naturally accompanied by the use of higher steam pressures; these made the use of boilers and turbines of higher capacity both possible and desirable. The use of these sets of larger capacity (as in all prime movers) brought down the capital cost per unit of output to an extent which outweighed the higher cost of the special materials of construction used to withstand the higher temperatures. The use of higher

1954 equivalent capital cost of steam power stations, £ per h.p.

Fig. 1

temperatures and the practicability (provided by the use of higher pressures) of using re-heat, increased thermal efficiencies and combined with the reduced capital cost to reduce the cost of generation.

To project this trend into the future we have to take into consideration other factors in design (such as transport of components to site) and in operation, such as the size and stiffness of interconnexion of the British electricity grid system.

Before we can use the forecast of capital cost and efficiency prepared in this way to predict the future cost of conventional power, we must also forecast the cost of coal. It is interesting to find that this forecast of future coal costs, depending as it does on competition from oil and nuclear fuels, on social habits, economic conditions and on Government policy, is far more uncertain than the forecasts of capital cost and thermal efficiency either in the conventional or the nuclear fields, great as are the uncertainties in both of them.

When these predicted coal costs are applied to stations having the capital costs which are forecast, we find that the cost of conventional power in future years will be as shown in Fig. 2. It is with these costs that nuclear power must compete.

Atomic energy does no more than provide a third fuel (alternative to coal and oil) which can be used in steam-power plants generating electricity. If, with this fuel, we could achieve the same top temperatures in the heat-cycle that are achieved with conventional fuels, nuclear power could to-day be cheaper than conventional power. That we cannot do so is obviously not due to difficulties in the boilers or turbines; it is due entirely to problems within the reactor. In descending order of difficulty these problems are concerned with the fuel elements, the moderator, the control of reactivity and the materials of engineering construction.

The top temperature achieved in the heat-cycle in nuclear power plants of the type favoured in the United Kingdom is determined by the bulk outlet temperature of the coolant gas from the reactor, and this is determined by the temperature tolerable in the hottest fuel element. The upward trend of the achievable temperature is shown in Fig. 3. In the Windscale reactors—built to a tight time-schedule for the production of plutonium for defence purposes—it was the temperature limitation in the fuel elements that made power production impracticable. For ease of manufacture and for nuclear economy, the fuel elements were 17 in. diameter rods of cast uranium enclosed in aluminium cans; the use of magnesium as a canning material was rejected partly because an early and inaccurate determination made its neutron absorption cross-section appear unattractive, but ultimately because of risk of fire in the reactor. When arrangements for manufacture were well advanced, the danger arising from formation of UAl_3 by interaction between can and metal was realized and dealt with by oxidizing the surface of the uranium bar and coating it and the inside of the can with colloidal graphite. This solution was satisfactory only for the modest conditions of the Windscale reactor, where the maximum surface temperature of the can was 300° C. and where (because of considerations connected with weapon design) the maximum irradiation of the fuel elements was less than 500 MW. days/tonne. Even at these low irradiations, the intercrystalline movement (due to heat-cycling a material in which the coefficients of expansion are greatly different in different crystallographic direc-

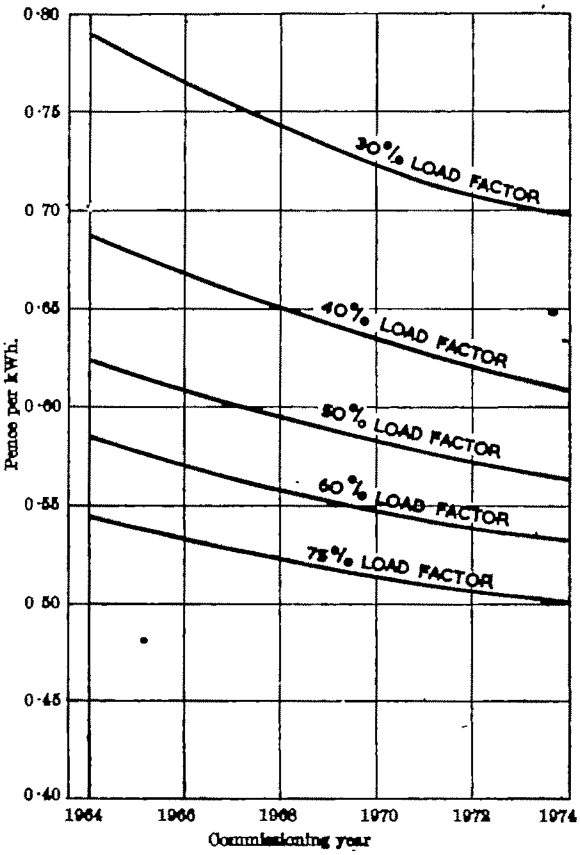

Fig. 2. Forecast of cost of electrical power from coal-fired stations at various load factors

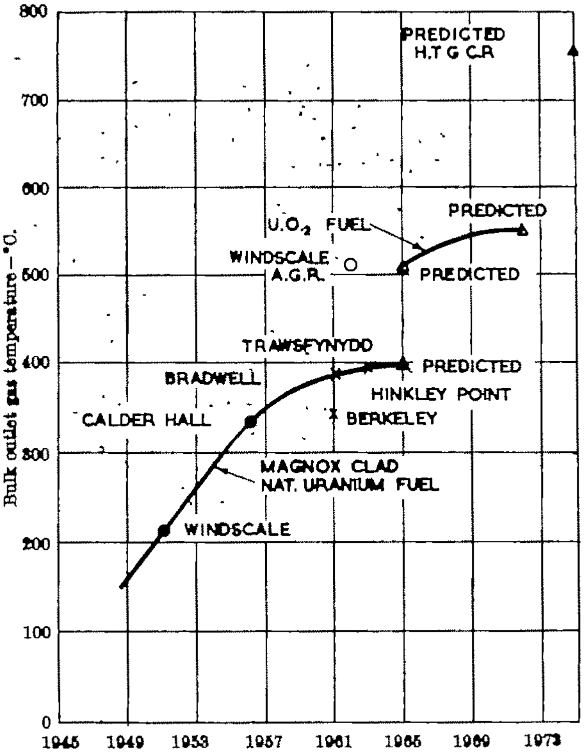

Fig. 3. The trend of outlet gas temperatures in British industrial reactors

tions and due to dimensional changes within single crystals caused by neutron irradiation) caused surface wrinkling which was liable to break down the barrier of colloidal graphite and permit metallic contact, formation of UAl_3 and can failure. Wrinkling was controlled by heat treatment to produce a fine random grain size; but the danger of the UAl_3 reaction, which increases with temperature, prevented advances while aluminium was used as a canning material.

It was the development of magnesium alloys containing small quantities of beryllium, calcium and aluminium to reduce the possibility of rapid oxidation and fire in the reactor which made the use of magnesium as a canning material practicable, and enabled us to reach outlet-gas temperatures which made power generation possible. But this magnesium alloy (magnox) has its disadvantages and limitations: at the operating temperatures in the cooler part of the reactor, it has a low elongation to fracture with low rates of deformation (a defect that can be minimized by careful design) and worse, it melts at about 640° C. Present reactor practice gives maximum surface temperatures of cans of 450° C. with possibilities of higher temperatures, so that little advance can be expected until change is made to another canning material.

Two alternatives are available to make the use of higher temperatures possible; stainless steel—cheap in itself but expensive overall because its high neutron cross-section makes enrichment of the fuel necessary—and beryllium, which gives economy of neutrons but it is an expensive metal.

The research by the Atomic Energy Authority on beryllium has been most ably done. When its development programme was started, little was known about the fabrication of beryllium; forming and joining techniques had to be found to give components of adequate strength and ductility. Techniques of consolidation and fabrication have been developed to the point where thin-walled tubes, rod, and forgings can be consistently produced to the close dimensional tolerances which are necessary. The mechanical properties of the fabricated metal are not the same in different directions (for example, the ductility of extruded metal is greatest in the direction of extrusion and is much smaller at right angles to this direction), and this has necessitated work to determine the metallurgical structure of the fabricated metal, with the view of optimizing the mechanical properties.

The high reactivity of the metal at elevated temperatures complicates the problem of joining, and it is necessary to use arc welding in argon or helium of high purity in order to achieve the desired results; as little as 0·05 per cent of oxygen in the welding atmosphere is sufficient to make the weld unsound. At high temperatures, beryllium is attacked by most metals and by carbon dioxide, and it is possible that this reaction may limit its operating temperature in reactors cooled with carbon dioxide to not much above 600° C. Energetic neutrons react with the nuclei of beryllium to form helium atoms within the crystal lattice, and these affect the mechanical properties of the metal and may limit its useful life in a reactor; an irradiation programme has been arranged to examine the problem and the first results are reasonably encouraging.

Further expansion in beryllium production will reduce the price, but it will always be expensive. Because of its high toxicity, great care is necessary in handling it; but experience shows that neither the scale nor the type of operation need be limited provided that the fabrication plant is properly designed. The problem of the poor ductility remains; but recent work suggests that the ductility is closely associated with impurities, and that this fault may be resolved by control of composition and by heat treatment.

Though the use of stainless steel or beryllium as a canning material opens the way to the use of higher temperatures, it means that in either case the cost per tonne of fuel elements will be far higher than with magnox. This increase must be offset by using higher ratings and by achieving higher burn-ups, both of which requirements force us away from the use of metallic uranium as a fuel.

In present practice the uranium centre temperature in the hottest fuel element is 590° C. Higher ratings necessarily mean higher temperature gradients, and when these are imposed on the higher temperatures of the surface of the cans that we must achieve, they bring conditions into the range where the phase change of the uranium will certainly cause trouble.

In reactors using metallic uranium fuel elements, we are hoping to achieve an average burn-up of 3,000 MW. days/tonne of fuel. It is improbable that figures much in excess of this will be achieved because (apart from distortion caused by crystalline movement due to irradiation and heat cycling) there is a volume increase due to the formation of fission products some of which are gases which can coalesce and cause swelling.

We thus find that to achieve the higher temperatures required, we are forced to use beryllium or stainless steel as a canning material; either course increases the cost of fuel elements. This must be compensated for by achieving higher ratings and higher burn-ups, and this can only be done by using uranium in ceramic form as our fuel.

Let us now consider the problems of the moderator. Graphite was used in the early stages of the U.K. project because we had no alternative. It has continued in use because it still seems to give the greatest economy in capital and operating costs; but its chemistry and physics under reactor conditions are still incompletely understood and it still presents a problem.

Reactor graphite does not oxidize quickly in carbon dioxide at temperatures below about 600–650° C. in the absence of radiation. In a pile, however, the carbon dioxide undergoes radiolysis with the production of active species which readily oxidize the graphite. This reaction causes a loss of graphite, with a consequent reduction of mechanical strength and moderating power; furthermore, carbon removed by oxidation may be deposited in the cooling circuit. The rate of reaction increases with the energy absorbed by the gas and thus with the gamma-ray flux and the gas pressure, and might, unless checked, become an embarrassment in advanced systems.

Studies of the reaction mechanism and methods of limiting the reaction-rate are being developed. One possible solution is to add to the coolant a gaseous inhibitor which will react preferentially with the active species. Carbon monoxide has proved to be effective, though it is possible that the benefit which has been observed is not caused by an inhibiting effect on the active species but by deposition of carbon produced by the radiolysis of carbon monoxide. A second possibility of reducing the attack depends on experimental evidence that most of the loss of weight is due to reactions on the internal surface of the graphite. It is probable that formation of active species occurs within the graphite pores (which constitute about 25 per cent of the volume of reactor graphite) so that the rate of reaction should be reduced by the sealing of these pores.

The physics problems of graphite result from the displacement of carbon atoms by fast neutrons having energy greater than the bond-energy in the crystal.

The first main effect is that the displaced atoms represent an accumulation of energy in the crystal; raising the temperature of the graphite partly anneals this damage, with liberation of the stored energy as heat. At low irradiation temperatures the energy stored in graphite can be considerable, and the Windscale reactors were periodically annealed in order to release this energy under controlled conditions. As the temperature of irradiation of graphite is raised, so the net damage to the graphite decreases, since under thermal activation a larger proportion of the displaced atoms return immediately to the vacant sites. The problem can be dealt with in practical reactor design by using moderator temperatures which, while sufficiently high to reduce the stored energy to tolerable levels, are well below the temperatures at which the chemical reaction between graphite and carbon dioxide becomes serious.

The second main effect is a change in the dimensions of the graphite blocks under irradiation. Displacement of carbon atoms causes the inter-planar spacing of the layers in the graphite crystal to increase and the layers themselves to contract slightly. These changes are integrated over the block (in which there is a preferred orientation of crystals) to give an increase in its transverse dimensions and a small shrinkage in the longitudinal direction. As with stored energy, the magnitude of this effect increases with the dose of radiation and decreases with rise of temperature. At temperatures of more than about 300° C., there is a second dimensional effect which, as yet, is not well understood and which gives rise to a contraction in both directions, possibly due to a closer packing of the crystallites. It is clear that there is still much research to be done on graphite under advanced reactor conditions.

Next in our descending order of difficulty as we advance in reactor technology were the problems of reactor stability and control, which become more acute when higher ratings and burn-ups are used. The basic reason for using gas-cooled instead of liquid-cooled reactors in 1946 was that they could not become instantaneously supercritical, and the large safety distances required by the original Hanford reactors were unnecessary. Operating experience showed that, with the low burn-ups used at Windscale, the reactors had a negative temperature coefficient and were, in fact, self-regulating. At higher burn-ups, however, the build-up of plutonium in the reactor reverses that part of the temperature coefficient which is associated with the graphite. This complicates the analysis, but the overall effect is that control must be by movement of the control rods, and care must be taken to see that departure from normality cannot be too rapid to be corrected with absolute certainty. The problem of xenon poisoning becomes more acute at higher ratings; it may cause oscillatory disturbances (which would be aggravated by the effects of build-up of plutonium), and it can also make it difficult to re-start the reactor after a shut-down. It is fortunate that the temperature coefficient of the fuel element remains negative and that it is strong enough to give an effective stabilizing influence in rapid transients.

Last and least in our order of difficulty were the problems of engineering construction, and these are mainly connected with the pressure system. The large pressure shells which are at present used in reaction construction demand thicknesses of plate so great as to minimize the opportunity for rolling and cross-rolling in fabrication, and there must be a danger of persistence of casting defects and coarse grain in the steel. Welding these thick plates is not easy and the problem of brittle fracture (which is increased by neutron irradiation) demands close attention in design, fabrication and operation. These problems are reduced by the use of higher fuel-element ratings because the dimensions of the pressure vessel for given heat-output are reduced. The use of higher bulk-gas outlet temperatures would give rise to other difficulties if the pressure shell were exposed to these temperatures, but designs can be evolved to avoid this.

It is this history and this present state of knowledge and development that has led the Atomic Energy Authority to the design of the advanced graphite reactor that is being built at Windscale as a prototype for the next logical step forward in technology. It is designed to achieve a bulk outlet gas-temperature of 510° C.; the gas flow is so arranged that the pressure shell is not exposed to this temperature but only to gas at a temperature of 320° C. which has passed through the heat exchangers. The design of the fuel elements is such that either beryllium or stainless steel can be used for canning, with uranium oxide fuel. The arrangement of the graphite moderator is conventional; the graphite loss due to corrosion during the life of the reactor is calculated to be tolerable, but more work is needed to check this point and to develop satisfactory conditions.

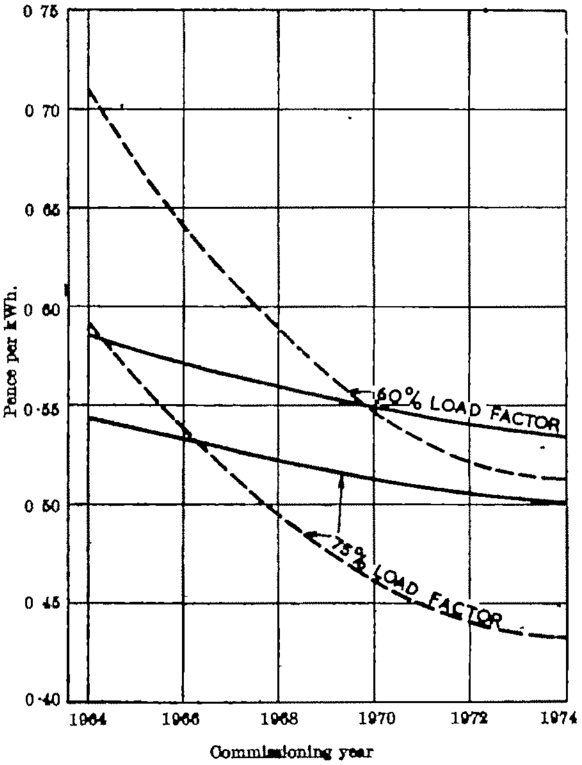

Fig. 4. Forecast of nuclear and conventional power costs in Great Britain. ---, Nuclear plant; ———, conventional coal-fired plant

It is estimated that the capital cost of the first industrial plant of the advanced graphite reactor type will be between £95 and £80 per kW. sent out, and that they will generate power at a cost of between 0·55*d*. and 0·50*d*. per unit or perhaps a little less at a load factor of 75 per cent; these cost brackets are naturally wide at a time when much development remains to be done.

The advanced graphite reactor represents the next logical step forward in British reactor practice; but, just as nuclear power finds strong competition from conventional power in establishing its new technology, so the new advanced graphite reactor must meet competition from the better established reactors of the Calder type in the early stages of its development. The advanced graphite reactor starts with the advantage of being able to achieve higher temperatures in its heat-cycle than are possible in magnox reactors, but in its race to supersede them it is competing with a technology which has advanced rapidly and is capable of further advance. Let us then look at the industrial progress of the magnox reactors with which the advanced graphite reactor competes.

The downward trend in cost of the nuclear power plants which are being built by the Central Electricity Generating Board in Britain can be closely estimated, and is shown in Table 1.

Table 1

Station	Capacity (MW sent out)	Cost (£/kW. sent out)
Berkeley	275 (2 reactors)	160
Bradwell	300 ,,	150
Hinkley Point	500 ,,	133
Trawsfynydd	500 ,,	128
Dungeness	550 ,,	110

This downward trend arises from the growing familiarity of the nuclear power industry with the problems of nuclear plant design and construction and from better overall optimization of design. It is difficult to separate these influences when considering individual designs, but from the general picture presented by the nuclear stations now being constructed three distinct lines of advance may be seen. These are, first, an increase of pressure in the gas circuit, secondly, improved utilization of the volume of the pressure vessel and, thirdly, increase in temperature of fuel elements and coolant.

A higher gas pressure leads to improved heat transfer from the fuel elements (allowing more power to be removed for a given fuel temperature limitation) and reduces the power required by the gas circulators. The higher the pressure, therefore, the greater the power that may be drawn from a given reactor. The coolant gas pressures for the Central Electricity Generating Board stations and for Calder are shown in Table 2, together with the pressure vessel dimensions and plate thickness.

Table 2

Station	Coolant pressure (lb./sq. in.)	Shape of vessel	Size of vessel	Thickness of plate
Calder	100	—	—	2 in.
Berkeley	125	cylinder	80 ft. high × 50 ft. diam.	3 in
Bradwell	132	sphere	67 ft. diam.	3 in. (some 4 in.)
Hinkley Point	185	sphere	67 ft. diam	3 in.
Trawsfynydd	239	sphere	61 ft. diam.	3½ in.
Dungeness	268	sphere	62 ft. diam.	4 in. (some 4½ in.)

This marked increase in pressure is due to the use of thicker plate for the pressure vessel and to the use of internal insulation in the hot-top domes. The effect of this latter advance in design is shown in a comparison between the system pressures of Bradwell and Hinkley Point, which have vessels of the same diameter and plate thickness. The greatly increased pressure at Hinkley Point is the direct result of internally insulating the top of the vessel, thus reducing its temperature and allowing a higher design stress. The increase in plate thickness follows naturally from the growing experience of welding and testing thick plate. This experience may be expected to lead to consideration of even thicker plate in the future.

Directly connected with this is the choice of shape of vessel—cylinder or sphere. As the reactor itself is of cylindrical shape, it fits most conveniently into a cylindrical pressure vessel and uses the volume of the vessel to the best advantage. Unfortunately, the allowable pressure in the cylinder is less than that for a sphere of the same diameter and plate thickness, and there is therefore a contest between utilization of volume and pressure in the system. The 'reactor cylinder' which has to be fitted into the pressure vessel includes the core itself, a cylindrical space above it which is needed to manœuvre the fuel-handling gear, and the heavy structure needed for the support of the core. Considerable design effort has been put into this structure to reduce its size and give a better shape, and hence a better utilization factor. How successful these efforts have been may be seen in Table 3.

This table clearly shows the better utilization possible with a cylindrical vessel and the considerable

Table 3

Station	Utilization factor (vol. of core/vol. of pressure vessel)	Shape of vessel
Berkeley	0·437	cylinder
Bradwell	0·313	sphere
Hinkley Point	0·406	sphere
Trawsfynydd	0·419	sphere
Dungeness	0·442	sphere

improvements that have been made in volume utilization in the spherical vessel.

The upward trend in temperature-levels is the result of better understanding of the heat-transfer process and better optimization of station design to make best use of this in terms of plant efficiencies. As the systematic and random variations in fuel-element temperatures become better understood, it becomes possible to design for operation nearer the limit set by the properties of the fuel-element materials. In short, the 'margin of ignorance' is being reduced and used to advantage. This is reflected in higher gas temperatures and improved steam conditions, as shown in Table 4; it must be remembered, however, that there is little more to be gained in this direction.

Table 4

Station	Gas inlet temp. (deg. C.)	Gas outlet temp. (deg. C.)	High-pressure steam conds. (lb./sq. in./deg C.)	Low-pressure steam conds. (lb./sq. in./deg. C.)
Calder	140	336	195/313	48/177
Berkeley	160	345	306/322	62/322
Bradwell	180	390	755/373	195/373
Hinkley Point	180	374	650/363	180/354
Trawsfynydd	202	399	962/382	304/368
Dungeness	250	410	1,403/393	575/395

All these developments help the nuclear station designer to move in the direction of obtaining more power from a given size of reactor and therefore to achieve a lower capital cost per kW. We may assess the results of his efforts in terms of reactor heat generated per unit volume of core. These 'heat densities' are set out in Table 5; they show clearly that the rate of development has been high.

Table 5

Station	Heat density kW./cu. ft. of core	kW./cu. ft. of pressure vessel
Berkeley	10·21	4·46
Bradwell	10·77	3·37

There can be little doubt that it would be possible to obtain 500 MW. of electrical power from a reactor of the Calder Hall type, using a pressure shell of about 70 ft. diameter with plate thickness about 4 in. At a time when the only operating experience is from the Calder Hall reactors with a capacity of 35 MW. electrical power, one shrinks from carrying the extrapolation in size so far, yet reactors with this capacity must be built in order to get the best results from the advanced graphite reactor and for comparative purposes a 500-MW. Calder type reactor should be considered. Using Calder Hall reactors of this size and assuming economies which can obviously be made in layout and general engineering of the stations, the capital cost should come down to about £100 kW., which should give a generating cost of around 0·52*d*. a unit.

The initial generating cost estimated for the advanced graphite reactor shows little, if any, immediate advantage over the Calder reactor developed in this way, yet all logic and history tells one that it is necessary to move forward to the type which gives a prospect of using higher temperatures. It is probable that, in these circumstances, there will be a period in which the two types overlap, and orders for advanced graphite reactor stations will be interspersed between orders for Calder type stations until ultimately the more technically advanced graphite reactor shows a clear advantage in operating cost over the older type. This would conform with practice in the conventional field, where advance to higher steam conditions has never implied that all new power plants used the most advanced conditions.

Based on these forecasts of development in design and downward trend of capital charges, estimates of fuel-element prices and operating charges, the cost of nuclear power has been forecast and is shown in Fig. 4. This figure also shows the forecast cost of conventional power and indicates that costs should break even between 1966 and 1970, depending on the load factor at which it is possible to operate.

It is disquieting, however, to compare the research and development effort which is devoted to bringing down costs in the two fields. In the conventional field, the available figures suggest that research and development costs are of the order of 5 per cent of the capital value of power plants built. Information is not available to determine the corresponding figure in the nuclear field but, if it is assumed that the cost of the nuclear sections (that is, the cost of the reactors and heat exchangers but excluding turbo-alternators and other conventional items) of the nuclear power plants built for the Central Electricity Generating Board in the years during 1965–75 is rather less than £50 million per annum, it seems improbable that research and development costs, if effort is maintained at its present level, are likely to be less than 30 per cent.

That research and development costs can be so high is easily understood when one considers the advanced gas-cooled reactor. It is probable that by the time the advanced graphite reactor goes into use, research and development expenditure on the development of the Windscale prototype will have been of the order of £30 million, and this is only one part of the effort required. It is unquestionably the logical step forward in British reactor technology, yet it is possible that the number of power stations built by the Generating Board to use this type of reactor will be less than ten.

By the mid-1970's, advance to higher temperatures and higher ratings is likely to make the introduction of another thermal reactor necessary. (This article does not consider fast-reactor development because it is felt that it is at present ancillary to the development of thermal reactors.) In the absence of developments which cannot at present be foreseen, it appears that we are reaching the limit of temperature and neutron intensity at which graphite can be used as an irreplaceable moderator, and that we shall be forced to types of reactor which make replacement or reconditioning of the moderator possible.

The high-temperature gas-cooled reactor which is at present in the project stage at Winfrith Heath (as a joint venture with other European countries) is an effort to meet the problem by using the graphite as the canning material for the fuel; it is thus replaced as the fuel elements are changed. Using enriched uranium in ceramic form in a semi-homogeneous system (which is capable of breeding), this reactor should, if it is successful, make it possible to achieve temperatures exceeding 1,000° C. in the heat cycle.

If such a system, using a replaceable graphite moderator, cannot be evolved, the alternative would be to use heavy water as a moderator, so that radiation damage can be repaired or removed during circulation. At that stage it would probably be convenient to use steam instead of carbon dioxide as a coolant. American reactor development has generally been on the lines of water-moderation and cooling. As they make their way towards higher temperatures in the heat-cycle, they will probably be forced to use steam cooling instead of water cooling. If this happens and if British development takes the line suggested, the two streams of development, starting so far apart, will have flowed logically together.

Meanwhile, we are faced with the fact that if the present rate of technological progress in the nuclear field is to continue, there appears to be little prospect that research and development costs will fall; they are likely to remain at about 30 per cent of capital expenditure.

For how long can the electricity industry justify this? The rate of advance in the nuclear field was determined initially by effort which was part of, and was justified by, the defence programme. Remembering that the demand for electricity has a doubling period of ten years, that the total fuel requirements of the Generating Board (expressed as coal equivalent) are now 54 million tons a year and will rise to 90 million tons a year by 1970, and remembering that it is improbable that sufficient British-mined coal would be available to meet the Board's total fuel requirement by some date in the 1970's, it appears reasonable to aim at continuing the high rate of advance of nuclear technology to the point where nuclear power breaks even in cost with conventional power; we shall then have freedom to manœuvre in a three-fuel economy. After that date, which is not remote, it is surely reasonable to think that research on reactor technology should be justified by savings which can be expected to arise from its industrial application. It is interesting to speculate how much the downward trend in the cost of conventional power could be increased if it could attract as great a research and development effort as its nuclear rival. There is no suggestion that it should attract such expenditure, but it is suggested that re-deployment of research and development resources must be carefully considered and that this consideration will probably demand a changed distribution in a few years time.

It is possible that there is, to-day, a danger that the deployment of research effort can be distorted by development work directed to defence and paid for by defence funds. Although work in the defence field may be directed to a few major projects, the ancillary work is widespread; for example, the development of nuclear weapons has demanded and fostered intensive and expensive research in ion exchange, solvent extraction, fluorine chemistry, vacuum technology, the metallurgy of a wide range of metals, the development of high-speed digital computers and other things. All these developments find industrial applications, so that the 'hot-house' growth of technology in the defence field affects the rate of development in many industrial fields where application is possible. When this happens only in the limited time of a war, the effect is beneficial; when peace returns, the injection of defence technology into industrial practice is a useful stimulus. But since 1946 conditions have been such that a war-time rate of development has continued in defence and its many ancillary fields, and one wonders whether the injection of these developments into the industrial field has not over-stimulated some industries in a way that makes it hard to live with them, while diverting effort from others. To avoid this would be difficult; but, as the emphasis of defence development moves from one field to another (and, one hopes, is ultimately relaxed overall), it is possible and desirable to examine the rate of advance which has been induced, and to ensure that it is adjusted to what is economically justifiable and that it does not continue by pure habit at a rate which is artificially high.

FOOD AND ANIMAL PRODUCTION

A SESSION on "Food and Animal Production Overseas", arranged by Section M (Agriculture) of the British Association, was held in Cardiff on September 2.

Mr. J. H. Anderson, of the National Agricultural Advisory Service, presented a rather gloomy picture of the present position of "Food Production Problems of the Middle East"—low rainfall, uncertain time of onset of the spring rains and, when it did come in quantity, the flooding of large areas and soil erosion.

For example, it had been calculated that in Iraq some 170 million tons of soil was carried down in the Tigris every year. Soil destruction by arable cultivations only and by over-grazing are leading to a worsening of the position. The average size of the holdings is small; for example, 90 per cent of the farms in Egypt cover less than 3 acres. In many cases these provide only enough food for the occupiers and none to supply the rapidly growing urban population. Throughout the area higher education tends to be directed to law rather than to technical training for the agricultural advisory or even medical services, there being only about two medical practitioners for every 3,000 inhabitants. He proceeded, however, under various headings, to describe what is being attempted and what is further needed to improve these conditions. Except for Egypt, better land and water-use is required: afforestation is wanted on the mountains. In Syria some 30,000 trees, in addition to windbreaks, are being planted to hold the water. In the discussion afterwards, it was mentioned that very deep ploughing with tractors, rather than the present shallow cultivation with wooden ploughs, would allow the water to sink in rather than run off or evaporate. Mr. Anderson also pointed out that it is increase in yield per acre which is required rather than increase in cultivated area. For this purpose nitrogenous fertilizers are one of the chief requirements, but the cost of importation is too great; Iraq is, however, setting up a nitrogen plant. Except for Turkey, Israel and Egypt, new improved varieties of crops with better yielding capacity are also required. Throughout the whole area, locust destruction is needed. Much more irrigation is required; great advances are being made in Israel, where it is hoped by 1975 to double the present area and triple the crop output. One problem with irrigation is increase in the salinity of the soil, some 70 per cent of the irrigated area in Iraq being more or less affected by this: research is needed in desalinating.

Livestock improvement is also wanted; except for Israel and Egypt, from cattle and buffaloes respectively, milk is in poor supply. To produce this, more feed from arable cultivation is necessary. In the other countries, the browsing goat is a useful source of milk supply. The need for tractors is great, but development in this respect is slow owing to the cheapness of labour. However, as pointed out in the discussion, tractors are necessary for deep ploughing on hard soil before the rains come. As in most places, a better system of agricultural credit should be made available to effect these improvements. Methods of helping the small farmer to accumulate capital were mentioned in the discussion on the paper by Mr. B. N. Chatterjee. Much could be done to improve food production in this area if the advisory services for farmers could be raised to a higher level and their personnel better trained.

Dr. J. Griffiths Davies, of the Australian Institute of Agricultural Science, gave an account of "Pasture Development of Tropical Australia". In the northern area the rainfall is a summer one, which ranges from 10 to 180 in. as one passes from the southern to northern tropics and from central to coastal areas. In general, the soil is poor and suffers from deficiency of nitrogen, calcium, phosphate and potash, as well as many of the trace elements too. Throughout most of the area cattle rather than sheep are the main product. Slides were shown of typical primitive vegetation areas and the methods used for their improvement. In areas of long dead grass, burning allows the young green shoots at the base to become available to cattle. In the acacia country, the bush is pulled over by chains between powerful tractors, piled, burnt and grass seed, such as that of Buffel and Rhodes grass, sown. One of the features of grass growth in tropical areas is the very rapid and luxuriant growth which occurs in the wet season; this, with the onset of the dry season, develops fibre and is low in protein and energy value for feeding purposes. During the discussion which followed, it was suggested that under such conditions the grass should be cut frequently during the wet season and made into silage for feeding during the dry season.

One of the main limiting factors for growth of grass throughout the tropical parts of Australia is the supply of nitrogen in the soil, and it is one of the most costly to apply, being about £39 per ton. Whereas in the south of Australia the application of phosphates and seeding with subterranean, strawberry or white clover supplies nitrogen for the grass, there are at present no suitable legumes for this in the northern areas; search for these is now in progress. Throughout the tropics, legumes, such as cow peas, etc., have been found for arable culture, but none suitable for incorporating into grassland has yet been used. Slides of some species which might prove suitable were shown; one came from Brazil and another from Guatemala. Various requirements are necessary in addition to their capacity for fixing nitrogen—a perennial character, palatability and non-toxicity for cattle. In addition to finding suitable species, there is also the problem of finding the right strain of organism to inoculate the seed. Slides were shown to illustrate the very large differences which exist in the growth of the legume due to this factor.

The importance of the problem is seen in the fact that there are some 90 million acres of poor soil in tropical Australia on which such legumes could be incorporated into the grassland.

Mr. B. N. Chatterjee, of the Department of Agriculture, Bihar, in his paper on "Animal Production and Fodder Resources in India", described the five main agricultural zones, conditioned mainly by rainfall and altitude, and compared the vast differences which exist between the level of nutrition of the people there and in the United Kingdom. Typical examples of some of the breeds of zebu cattle were shown. The two dairy breeds, the Sindhi and Sahiwal, are small, both in size and numbers, but they give reasonable quantities of milk. Some dual-purpose work-milk types exist, but for the most part the breeds in India are specialized for draught purposes. Buffaloes supply much more milk than cattle and their milk contains some 7·5 per cent of fat. Goats, too, are used widely as sources of milk and meat supplies.

Three main systems of animal husbandry exist. The State breeding farms form the main and practically the only source of livestock improvement. As was pointed out in the discussion, these are not large enough or numerous enough for the work that needs to be done in improving the milk yields of their cattle. The village farms, which are very small, provide little more than draft bullocks and barely enough milk for their own needs. Thirdly, there are the nomadic herdsmen, mainly with sheep and goats which are folded on crop residues and graze marginal land. For the most part, feed for animals is supplied from crop residues, many of which contain large quantities of fibre. The village grazing areas are overstocked and provide more exercise than nutrition. The growing of fodder crops and the making of silage for the dry season are badly needed, while the killing of the older cattle in necessary to allow of a higher nutritive level for those which have a productive value.

In the discussion which followed, it was pointed out that not only would the production of more milk in the villages and its collection by organizations in nearby towns such as that existing in Poona, be of advantage to the nutrition of the urban population, but also the weekly income derived from it would keep the villager out of debt, so that when his crop came to be harvested it would be his and not the moneylenders. Moreover, if more milk were consumed, it would have a sparing action on the need for cereals, and so some land could be released to grow fodder crops, after which the yields of cereals would be higher. In pig-feeding experiments in England, it has been shown that it requires some 5 lb. of cereals to produce 1 lb. live weight, whereas when a little animal protein such as milk is added, this is reduced to about 4 lb. The question of whether the essential amino-acids in animal protein could be added to extracted leaf protein is at present out of the question, owing to the high cost of the synthesized products.

During the course of the discussion, Prof. J. Grossman from Brazil gave a short illustrated account of the agricultural zones there. The projects for irrigation in the highly populated areas were mentioned. The grassland areas in the south with a 60-in. rainfall could, with phosphates and clovers, produce suitable feed for cattle. While in the far south European breeds of cattle can be kept, farther north it is necessary to use zebu cattle. Recently, however, improved beef types which are tolerant of heat, such as the new Santa Gertrudis breed from Texas, have been introduced.

JOHN HAMMOND

GROWTH BY CELL DIVISION IN INSECT TISSUE CULTURE

By DR. B. M. JONES and I. CUNNINGHAM
Department of Zoology, University of Edinburgh

THE cultivation of insect tissues and cells, first attempted about fifty years ago[1], has been an unexpectedly difficult problem[2-4]. A method for the routine production of insect cultures in a medium that can be easily prepared, and the provision of adequate evidence of growth by cell division taking place in them as in vertebrate cultures, has not hitherto been available[4]. The delay in devising such a method arises largely from pioneer work having to rely on knowledge of the requirements that favour the growth of vertebrate tissue in culture[5]. Recently, however, encouraging results have been obtained in maintaining insect tissue in a physiological solution based on the composition of insect hæmolymph[6,7], which differs profoundly from that of the blood of vertebrates[8-11].

The purpose of this article is to describe briefly the results of an investigation undertaken to try to devise a method of producing insect tissue cultures in a routine fashion, and to evaluate in particular the extent and nature of growth by cell division in the cultures obtained. The work is based on the use of diapause pupæ of the silkmoth, *Philosamia advena*, as a source of ovarian tissue for explants, and of hæmolymph for inclusion in the culture medium. It so happens that development in these pupæ is arrested for about six months extending from the autumn to the early summer, a period that can be lengthened if need be by storing the pupæ continuously at 25° C. (ref. 12). The pupæ, in providing tissue in a more or less uniform state over such a long period, thus favour the design of a method of producing insect tissue cultures as required. So does the use of a medium that can be prepared easily. The one employed in the present work consisted essentially of salts, sugars and organic acids, based on previous work[6], lactalbumin hydrolysate ('Difco'), *TC* yeastolate ('Difco'), and pupal hæmolymph. The latter was preheated before it was added to the medium[6]. The usual precautions were taken in preparing hanging-drop cultures to ensure freedom from contamination. Streptomycin and penicillin were also added to the medium at 100 I.U. and 50 I.U. per ml., respectively (Table 1).

Table 1. COMPOSITION OF THE MEDIUM FOR THE CULTIVATION OF OVARIAN TISSUE OF THE DIAPAUSE PUPA OF THE SILKMOTH *Philosamia advena*

		Mgm./ 100 ml.			Mgm./ 100 ml.
A.	NaH_2PO_4	110	*D.*	Malic acid	60
	$MgCl_2.6H_2O$	300		Ketoglutaric acid	35
	$MgSO_4.7H_2O$	370		Succinic acid	6
	KCl	300		Fumaric acid	5.5
B.	$CaCl_2$	80	*E.*	*TC* yeastolate ('Difco')	100
C.	Glucose	70			
	Fructose	40	*F.*	Lactalbumin ('Difco')	1,000
	Sucrose	40			

The salts were dissolved in 30 ml. water; calcium chloride in 7 ml. water; sugars in 10 ml. water; organic acids in 5 ml. water and neutralized with potassium hydroxide. Lactalbumin was dissolved by autoclaving at 10 lb. pressure for 10 min. in 35 ml. water; *TC* yeastolate in 5 ml. water. The solutions were mixed, adding the calcium chloride last. *p*H was adjusted to 6.35 with 10 per cent potassium hydroxide, and then pre-treated hæmolymph was added, and finally antibiotics. See text for further information.

In the preparations incubated at 25° C., cells began to migrate from the explants on about the third day, and from the fourth to ninth days the cellular outgrowths spread extensively over the surface of the coverglass (Fig. 1). The medium was changed every fifth day. The cultures remained healthy for up to four weeks, and in appearance they resembled primary chick fibroblast cultures.

To permit an estimation of growth by cell division in the outgrowths, and to ascertain the nature of the cells involved, a technique was devised for making permanent stained preparations of cultures *in situ*. Adhesion of the explants and the outgrowths to the coverglass, an important requirement for carrying it out successfully, was greatly favoured by the presence of 10 per cent hæmolymph in the medium, and by inverting the culture chambers during incubation.

Examination of such preparations revealed that several kinds of cells originating from the different

Fig. 3. Prophase in ovariole sheath cell in cellular outgrowth stained with Erhlich's hæmatoxylin *in situ*, 9 days. Fig. 4. Metaphase in same kind of cell in outgrowth, 9 days. Fig. 5. Late anaphase, 9 days. Fig. 6. Metaphase, 12 days. Fig. 7. Early anaphase, 12 days. Fig. 8. Telophases displayed by cells derived from the intermediate layer of the ovariole, 9 days. Fig. 9. Cells of intermediate layer in outgrowth almost completely divided, 9 days. (The number of days refers to age of culture)

regions of the ovary, long ago described in detail[13], were present in the outgrowths, those of the ovariole sheath and of the intermediate layer of the ovariole tubule being predominant (Fig. 2). It was less easy to be certain of the presence of cells of the inner follicle layer; but it is likely that these cells only escape into the medium when their bounding membrane is impaired in the explant. Occasionally, the extremely large nurse cells wandered out into the cellular field. Brush-like extensions composed of cells derived from the connective tissue cap, which encloses the distal portions of the ovariole tubules, and epithelial sheets formed by cells of the ovariole sheath, often appeared in the cultures prior to the migration of discrete cells. It has been suggested that hæmocytes might be present in the outgrowths[14], and it would be interesting to learn to what extent they are involved.

Mitosis in the outgrowths was mainly confined to the cells of the ovariole sheath, and those of the intermediate layer. These cells, scattered in the cellular field, displayed mitosis at all stages (Figs. 3–9). In cultures 5–6 days old the mean mitotic index was 1·0 per cent, in those of 8–9 days 0·5 per cent, 12 days 0·3 per cent, and 21 days less than 0·3 per cent. From an estimated mitotic index of 0·5 per cent over a period of 12 days, and also from the fact that cells in culture took 30 min. to divide, one may infer that the cells that were capable of mitosis produced several generations during this period. Mitosis in cultures three weeks old also supported the conclusion that growth by cell division was progressive and therefore resembled that which takes place in primary cultures of vertebrate tissue.

It is hoped to publish the details of this work, which was made possible by a grant from the Agricultural Research Council, elsewhere in due course. We thank Prof. Michael Swann for helpful discussions, Dr. Honor Fell for the interest she has shown in this work, Dr. John Campbell for taking photographs of mitotic figures in our preparations, and also Mr. Dennis Cremer for his help in the photography.

OBITUARIES

Prof. H. Moore

EMERITUS PROF. HARRY MOORE died on August 5 at the age of seventy-two. He was educated at Belle Vue School, Bradford, and the Royal College of Science, London, where he was afterwards demonstrator, and then lecturer, in physics at King's College, London, during 1908–15. During this period he published papers on the ionization produced by X-rays in various materials.

He was a very capable craftsman and he turned this talent to very good war-time use when during 1915–18 he was co-manager of the Munitions Training Department at King's College, London. There followed a short period as technical officer to the Training Department of the Ministry of Labour, but in 1919 he joined Sir Herbert Jackson in the newly formed British Scientific Instrument Research Association. It was here that his interest in glass was first aroused, and he was responsible with Jackson for a programme of research, particularly on optical glasses, which had originally been sponsored by a war-time Committee for Glass Research of the Institute of Chemistry. In 1933 he followed Sir Herbert Jackson as director of research of the British Scientific Instrument Research Association, a post which he held for four years, and in 1937 became director of the Research Laboratories then being set up by Pilkington Brothers, Ltd., in St. Helens. This post he held from 1937 until 1945, and during this time he became very active in circles concerned with glass technology, serving as president of the Society of Glass Technology during 1944–46.

Moore was appointed to the chair of glass technology in the University of Sheffield when W. E. S. Turner retired. The Department was set up in 1915 with the function of teaching in the subject of glass technology and with carrying out investigations and research on problems connected with industry. It was governed by a body known as the Glass Delegacy, the members of which were about equally divided between the University and industry. This unique arrangement had functioned extremely well during the period in which Turner held the chair, and while the number of University students was small. After the Second World War, the growth of the Department's teaching work and the demands on its time by industrial inquiries soon convinced Moore that some change in its structure would eventually be needed, and when he retired in 1955 the Delegacy, under the chairmanship of Dr. L. H. A. Pilkington, had just completed arrangements for the setting up of the new British Glass Industry Research Association. These arrangements left the University Department free to carry out teaching and research exactly as a normal university department.

In addition to the duties of his chair, Prof. Moore had been dean of the Faculty of Engineering for the three years, 1948–51. While head of the Department of Glass Technology, Moore's chief research work was concerned with the colours of glass and particularly those due to iron; a fascinating problem which, apart from its technological importance, for iron is an ever-present impurity in all raw materials used for glass making, has great scientific interest.

Shortly after Moore retired, the Society of Glass Technology found itself without an editor, and he allowed himself to be persuaded to step into the breach. Once having been persuaded, he threw himself into the task with characteristic energy and attention to detail for a period of eighteen months. Towards the end of this period, however, he seemed to realize that he was no longer a young man, and after a short period in hospital, he and Mrs. Moore decided to move south and, as he himself put it, "to rusticate completely". In September 1958 they moved to Arundel, where his younger son had been living for a year or so. The move was a success and it is pleasant to think that he and Mrs. Moore had two years of quiet retirement together.

The University of Sheffield and the glass industry will always be conscious of the great debt it owes to Harry Moore for his energetic leadership and wise guidance of the Department of Glass Technology at a critical period of development and decision.

R. W. Douglas

Walter Baade

With the death on June 26 of Walter Baade, astronomy loses a truly outstanding figure.

Some thirty years ago, it was generally expected that Baade would succeed to the directorship of one of the major German observatories. But this was not to be. In 1932, at the suggestion of Edwin Hubble, Baade was offered a two-year fellowship at the Mt. Wilson Observatory. His knowledge of astronomy proved so comprehensive, and his telescopic technique so perfect, that this temporary arrangement soon became permanent. Baade remained a staff member of the Mt. Wilson and Palomar Observatories until retirement two years ago.

At the time of his emigration, Baade was perhaps best known for his work on Cepheid variables. 'Baade's criterion' is still spoken of in the subject.

In a short space, only the briefest mention can be made of his outstanding contributions. There was work on supernovæ, first with Zwicky, then with Minkowski. Baade's supremacy as an observer was widely acclaimed after his brilliant resolution in 1944 of stars in the nucleus of the Andromeda Nebula. In his contribution to the dedication of the 200-in. Palomar telescope, he clearly foresaw the great contribution that the colour-magnitude diagrams of star clusters would make to the understanding of stellar evolution. Perhaps his most famous piece of work was his re-assessment, some ten years ago, of the distance scale of the universe. Outstanding in recent years has been the optical identification, in collaboration with Minkowski, of cosmic radio sources.

Almost every one of Baade's papers turned out to have far-reaching consequences ; and much has died with him.

Fred Hoyle

NEWS and VIEWS

Biochemistry at Leicester : Prof. Hans L. Kornberg

Dr. Hans L. Kornberg, who has been appointed to the newly established chair of biochemistry at the University of Leicester, has distinguished himself especially by a series of papers on the metabolism of simple carbon compounds in micro-organisms. He has made major contributions to the elucidation of the pathways leading from acetate and more highly oxidized carbon compounds to cell constituents when such compounds serve as the sole source of carbon. Dr. Kornberg was educated at Queen Elizabeth Grammar School, Wakefield, and the University of Sheffield. He started his postgraduate career in the Department of Biochemistry at the University of Sheffield in 1949 after graduating in the Honours School of Chemistry. In 1953 he was awarded a Commonwealth Fund fellowship, which he spent in the laboratories of Dr. E. Racker of Yale University and the Public Health Research Institute of the City of New York, and of Dr. M. Calvin at the University of California. Since 1955 he has been a member of the staff of the Medical Research Council Unit for Research in Cell Metabolism at the Department of Biochemistry, Oxford, where he has headed a very active research group including many visitors from overseas.

Botany at St. Andrews : Prof. J. A. Macdonald

Dr. J. A. Macdonald has been appointed professor of botany at the University of St. Andrews in succession to Prof. J. H. Burnett, who is taking the chair of botany at King's College, Newcastle-on-Tyne (see *Nature*, 186, 1016 ; 1960). The appointment of Dr. J. A. Macdonald, who is at present senior lecturer in the Department of Botany at St. Andrews, will bring pleasure to a wide circle of botanists, not least to those in Scotland. His appointment ensures the continued happy development of the department, and the Botanic Garden, much of which was initiated by him during 1950–55 as acting head of the department. Born at Dingwall, Dr. Macdonald was educated successively at Paisley, Inverness Royal Academy and the University of Edinburgh. He obtained the B.Sc. (Agric.) with honours in botany in 1931, and the Ph.D. in 1935. He was then appointed lecturer in botany at St. Andrews and senior lecturer in 1953 ; in 1947 he was awarded the Sykes Gold Medal for his D.Sc. thesis. Elected Fellow of the Royal Society of Edinburgh in 1940, he has served on the Council since 1956 ; during 1955–57 he was president of the Botanical Society of Edinburgh. Dr. Macdonald's special interests are in fungal cytology, the general biology and life-cycles of rust fungi and pathogenic fungi. He has brought to these studies the very needful qualities of healthy scepticism, great tenacity and patience. His work has stimulated interest in the somewhat neglected field of somatic fungal cytology. To his teaching Dr. Macdonald brings humour and good sense ; to his University, loyalty and a wide acquaintance with university administration ; to his colleagues and students, friendliness and understanding. He will take up his appointment on January 1, 1961.

U.K. Agricultural and Food Attaché in Argentina : Mr. A. G. Mill

Mr. A. G. Mill, a livestock husbandry advisory officer of the National Agricultural Advisory Service, has been appointed agricultural and food attaché on the staff of the British Embassy in Buenos Aires, in succession to Mr. R. H. Smyth, who has retired. Mr. Mill was educated at Warwick School and Harper

Adams Agricultural College. During 1929–38 he worked for Liebig's Extract of Meat Co., in Argentina. He joined the Ministry of Agriculture and Fisheries in 1939 as a livestock officer. During 1945–49 he was loaned to the Colonial Office for service with the Government of Barbados. On his return to the Ministry in 1949, Mr. Mill was appointed agricultural attaché in Buenos Aires where he served until 1952, having led the United Kingdom delegation to the Inter-American and Food and Agriculture Organization Conference in Monte Video, Uruguay, in 1950. Since 1952 he has been a livestock husbandry advisory officer of the National Agricultural Advisory Service, stationed in the West Midland Region.

Future of Broadcasting in Great Britain

THE Committee on Broadcasting under the chairmanship of Sir Harry Pilkington is ready to receive representations. The terms of reference of the Committee are: "To consider the future of the broadcasting services in the United Kingdom, the dissemination by wire of broadcasting and other programmes, and the possibility of television for public showing, to advise on the services which should in future be provided in the United Kingdom by the B.B.C. and the I.T.A.; to recommend whether additional services should be provided by any other organization, and to propose what financial and other conditions should apply to the conduct of all these services". Any person or organization desiring to submit evidence or to make representations to the Committee should address them in writing to the Secretary, Committee on Broadcasting, G.P.O. Headquarters' Building, St. Martin's-le-Grand, London, E.C.1, as soon as possible, but not later than November 30.

Electronic Equipment in the French Nuclear Energy Industry

No. 3 in the Review Series published by the International Atomic Energy Agency, Vienna, is entitled "Electronic Equipment used in the Nuclear Energy Industry in France" and is in French with English, Russian and Spanish translations of the introduction and table of contents. The authors, P. Desneiges, M. Doireau, L. Koch and J. Weill, are members of the staff of the Centre d'Etudes Nucléaires, Saclay, and the subject-matter refers particularly to French practice, though much is common to other countries and equipment similar to that described is available in many places. The four sections of the review deal respectively with basic electronics equipment for laboratories, such as rate meters, pulse-height analysers and personnel monitoring instruments, and their standardization; specialized equipment, including particle detectors of various kinds and complex electronic equipment for carbon-14 and tritium measuring techniques; reactor control equipment, including neutron detectors, amplifiers, servo-mechanisms and electronic computers; and special applications of nuclear electronics involved in prospecting for uranium minerals, the control of the chemical processing of plutonium and fission products and the detection of leakage of fuel containers. Details of circuitry are not given; but a comprehensive list of references at the end of the Review includes reviews covering specific aspects and a catalogue published by the French atomic energy authority which contains data on commercially available nuclear electronic instruments.

Report of the Government Chemist

THE report of the Government Chemist for 1958–59 (London: H.M.S.O., 1960. 3*s*. 6*d*. net) contains accounts of a wide range of subjects studied during the period stated. The responsibility for this Laboratory, previously known as the Government Chemist's Department, passed from H.M. Treasury to the Council for Scientific and Industrial Research on July 1, 1959, and the report covers the period from April 1958 to December 1959. An interesting discovery is that of the poisonous alkaloid solanine in dangerous amounts in early new potatoes imported from the sub-tropics. The formation of persistent foams in sewage treatment and in rivers, resulting from the use of synthetic detergents, has been fully investigated and the report contains much information on this subject. The use of alternative material is likely to mitigate the trouble.

Accidents in Mines and Quarries

THE annual reports of H.M. Divisional Inspectors of Mines and Quarries for 1959 (London: H.M. Stationery Office) for each of the eight divisions (Scottish, 3*s*. 6*d*. net; Northumberland and Cumberland, 2*s*. 6*d*. net; Durham, 3*s*. 6*d*. net; North Eastern, 3*s*. 6*d*. net; North Western, 3*s*. net; East Midland, 3*s*. 6*d*. net; West Midland and Southern, 3*s*. 6*d*. net; and South Western, 2*s*. 6*d*. net) have been published at intervals during the past few months. The reports deal with accidents and their prevention, dangerous occurrences, ventilation, safety organization, training, education, health and welfare in connexion with all mines and quarries in Britain. Most of each report concerns coal mines, with emphasis on accidents, dangerous occurrences and safety. Accident-rates, fatal and non-fatal, from all causes show improvements in some divisions, compared with averages for the past three years, but not in others. During 1959 the number of men killed in coal mines varied, among the divisions, from 0·47 to 5·03 per million tons mined, while the number killed per thousand workers varied from 0·18 to 1·13; the corresponding figures for serious non-fatal accidents were 4·62 to 15·01 and 1·97 to 3·17. Except in one division, where 47 men were killed in an underground fire, more accidents at coal mines were due, as usual, to falls of ground than to any other single cause and, over Britain as a whole, accounted for 142 deaths out of a total of 348 and for 710 serious non-fatal accidents out of a total of 1,676. Mining is hazardous; but it is clear from these reports that the accident-rates could be much reduced by adherence to rules and application of good sense.

Introducing Atomic Energy

A SERIES of articles entitled "A Plain Man's Guide to Atomic Energy" is being contributed by P. J. Dunston, the director and general manager of (Heston) Fairey Engineering Ltd., to the quarterly magazine *Fairey Review*. In the first article an outline was given of the general structure of matter and the relationship between matter and energy, and in the second article which appears in the current issue (3, 36; June 1960) radioactivity and the release of nuclear energy are discussed. Reference is made to the classic investigations of the Curies, Rutherford, and Cockcroft and Walton, but the opportunity is taken to mention and to give illustrations of modern methods and equipment for handling and machining radioactive materials. A coloured chart of the elements including all known isotopes, with stable and unstable isotopes and nuclear isomers shown separately, and with two typical radioactive-decay chains, accompanies the article. (Uncreased copies of the chart may be obtained from Fairey Engineering Ltd., 24 Bruton Street, London, W.1.) The third article in the series will deal with the interaction of neutrons with matter and the general economy of neutron production in a fission reaction.

Strontium released from the Windscale Accident

It is perhaps surprising to find another publication on the Windscale reactor accident in October 1957. However, a recent joint report by the United Kingdom Atomic Energy Authority and the Agricultural Research Council, entitled "The Deposition of Strontium-89 and Strontium-90 on Agricultural Land and Their Entry into Milk after the Reactor Accident at Windscale in October 1957", provides a useful reassurance that radiostrontium from the reactor was probably not deposited on the ground in biologically significant quantities (Report AHSB (RP) R2. Pp. ii+26+5 plates. London: H.M. Stationery Office, 1960. 5s. net). The concentrations of strontium-89 and strontium-90 in herbage, root-mat, soil and milk are given in detail for no less than thirteen farms. Only for farms within a 2-mile radius of the factory was it possible to conclude that strontium-90 had come from the Windscale reactor. The highest value recorded, in a field adjacent to the pile, was some sixty times the national average, although a large proportion of the material on this field apparently resulted from emissions prior to October 1957. For farms at distances of 8–20 miles, it could not be established with certainty that the levels were measurably higher than for other parts of Great Britain, where all the strontium-90 is presumed to be the result of nuclear weapon testing. The highest concentration in any of the milk samples from the 'near-in' farms was 11 per cent of the maximum permissible level allowed by the Medical Research Council for reactor accidents. There is a further reassurance in evidence which suggests that the incorporation into food chains of radiostrontium released from the pile is only about one-third of that reported for bomb-produced strontium.

Helium-4 Scale of Temperature

At the meeting of the International Committee of Weights and Measures held in Sevres, during September 29–October 3, 1958, the recommendation was adopted that the '1958 Helium-4 Vapour Pressure Scale of Temperatures', based on a vapour pressure table arrived at by international agreement and co-operation, should be used as the international standard scale of temperature between 1° and 5·2° K. A recent publication by F. G. Brickwedde, H. van Dijk, M. Durieux, J. R. Clement and J. K. Logan, issued by the U.S. National Bureau of Standards, describes the new scale in detail (Monograph No. 10. Pp. ii+17. (Washington, D.C.: Government Printing Office, 1960.) 20 cents). In Part 1 of the monograph, F. G. Brickwedde discusses the three practical methods for the determination of the helium-4 vapour pressure–temperature relation, and the various measurements made, and scales adopted, prior to 1958. Following discussions at Leyden between members of the Kamerlingh Onnes Laboratory and the National Bureau of Standards in June 1958, the Scale and the table of helium-4 vapour pressures later adopted by the International Committee of Weights and Measures were agreed on. The table was distributed at the Kamerlingh Onnes conference on "Low Temperature Physics" held at Leyden during June 23–28, 1958, and was published in the conference proceedings. The vapour pressures were listed at 1/100 degree intervals. The table has since been expanded by Clement and Logan, and the expanded table forms one of the seven tables presented in Part 2 of the monograph. In addition to the vapour pressure of helium-4 (1958 Scale) in microns (10^{-3} mm.) mercury at 0° C. and standard gravity (980·665 cm. sec.$^{-2}$) there are listed the 1958 helium-4 vapour pressure-temperature scale, T in deg. K. as a function of pressure P in mm. mercury, and, for $P > 80$ cm., in cm. mercury, at 0° C. and standard gravity; dP/dT in mm. mercury per deg. K.; an auxiliary table for use in making hydrostatic head corrections; deviations of earlier scales from the 1958 Scale; and an auxiliary table for use in making corrections for the density of mercury at temperatures other than 0° C. Fixed points on the '1958 Helium-4 Scale' are the boiling point at 4·2150° K. and the λ-point at 2·1720° K., for $P = 760{\cdot}00$ mm. mercury at 0° C. and standard gravity, and the critical point at 5·1994° K. if the critical pressure is taken to be 1,718 mm. mercury at 0° C. and standard gravity.

High-Temperature Furnaces

A new range of electric furnaces for use in the laboratory, workshop or tool-room is described in Messrs. A. Gallenkamp and Co. Ltd.'s catalogue No. 620 which has recently been issued. Operating temperatures have been increased and box and tube furnaces are now available for use up to 1500° C. The smallest muffle furnace, the 'Super Hotspot', is a moderately priced, versatile furnace for general laboratory work at temperatures up to 1100° C. The refractory muffle which is wound externally with a high-grade resistance-wire heater is fitted in a non-corroding 'Asbestolite' case of smooth surface by refractory insulating bricks. There are built-in controls and pyrometric equipment, together with a safety fuse to protect the heating element against accidental overheating. The larger muffle furnaces are available in three sizes, and together with the 'Super Hotspot', have internal sizes ranging from 4 × 5 × 6 in. to 8 × 9 × 18 in. The box furnaces are similar to the muffle furnaces, but with 'Crusilite' elements for temperatures up to 1400° C. and with 'super' elements (chiefly molybdenum disilicide) for temperatures up to 1500° C. Tube furnaces with 'Crusilite' and 'super' elements are also available. Two sizes, 4-in. diameter and 9-in. high, and 6-in. diameter and 15-in. high, of vertical-tube crucible furnaces have been introduced. They have wire elements wound on grooved refractory tubes and have built-in manual controls and temperature indicators. Other types of furnaces described in the catalogue include a high-temperature vacuum furnace, ash furnaces, and Gray-King furnaces for coal and coke analysis.

The Tungusska Meteorite

The problematic Tungusska meteorite, which fell on June 30, 1908, is still a subject of discussion (V. N. Rodionov and M. A. Tsikulin, *Priroda*, 11, 84; 1959). It is marked by an elliptical area of full tree-fall, 25 × 10 km., surrounded by a zone of a partial tree-fall, 50 × 40 km. As suggested previously, this devastation is due to the impact of the shock-wave, as no fragments of meteorite itself were ever found. It is suggested by the present authors that the meteorite may have disintegrated and the fragments fallen in the front of the partial tree-fall. On the other hand, B. I. Vronsky (*Priroda*, 3, 88; 1960) suggests, first, that the meteorite in question may have been a stone, and not an iron meteorite; and secondly, that the numerous water-logged hollows, so abundant in this area, may indeed represent impact craters of the meteorite fragments now deeply buried in the bog. Finally, E. L. Krynov, a foremost authority on meteorites (*Priroda*, 5, 57; 1960), does not agree with either view and is inclined to accept the hypothesis originally advanced many years ago by I. S. Astapovich and F. L. Whipple (*Priroda*, 9, 70; 1935), who have suggested that the Tunguska tree-fall was not due to the impact of a meteorite, but of a small comet containing a core of ice which had embedded in it meteoric matter.

Dispersion of Small Bodies

DR. D. O. WOLFENBARGER has prepared a scholarly review of the dispersion in space of small bodies (*Lloydia*, 22, No. 1, 1; 1959). In this paper he covers work published since the appearance of his earlier account, published in 1946. His aim has been to describe and analyse quantitative and objective results published on this topic. This is done with the help of 194 graphs which accompany the examples discussed. The types of unit dealt with are inorganic salts, viruses, fungi, pollen, molluscs, water-fleas, and insects, including grasshoppers, mosquitoes, flies and bees. The agents of dispersal include air currents, water, other organisms, growth, and automotility. The distances involved extend from less than 1 mm. from the source, reached by basidiospores of *Puccinia malvacearum*, the principal agent being gravity, up to the 140 miles covered by some tsetse flies by means of hitch-hiking on trains. In a discussion of the results, Dr. Wolfenbarger considers the achievements of dispersion in the biology of organisms, the details of sampling and measuring, and the endogenous and exogenous factors associated with varying distances of dispersion. There is much in this review that is relevant to plant, animal and human epidemiology, allergy, population genetics, plant breeding, and plant and animal ecology.

Search for Oil in Britain

IN 1937, G. M. Lees and P. T. Cox described a geological basis of oil prospecting in England as then envisaged. This was followed by a report on exploratory work by G. M. Lees and A. H. Taitt (1946), wherein particulars were given not only of the discovery of four new oilfields, but also of new geological information of high academic and economic significance. The search still goes on. A recent Memoir (1960) of the Geological Society, by N. L. Falcon and P. E. Kent, presents geological results of petroleum exploration in Britain by the British Petroleum Company during the years 1945–57 (Memoir No. 2: Pp. 56+5 plates. (London: Geological Society of London and H. K. Lewis and Co., Ltd., 1960.) 25s. net). Altogether eleven oil-producing areas have been established, with a cumulative production total, to the end of 1959, of more than 1·25 million tons. The latest fields are Plungar (Leicestershire) and Egmanton (Nottinghamshire); prospects are at Bothamsall, an extension of Eakring (discovered in 1939), and at Corringham, near Gainsborough. Other possibilities have been and are being pursued in which the well-tried techniques of reflexion seismic exploration and electric logging have been successfully exploited. It is noteworthy that gamma-ray logging proved to be of considerable help in sub-surface correlation of marine-band markers in the East-Midlands projects. Economically important also is that the pattern of oil prospecting as originally delineated has been extended to include search for natural gas, jointly on behalf of the Gas Council and Imperial Chemical Industries, but with what measure of commercial success has yet to be determined.

Freeze-drying of Plant Viruses

WHEREAS freeze-drying has been widely and successfully used for the preservation of bacteria, animal viruses and bacteriophages, there appear to have been relatively few attempts to conserve viruses by this means. It has been ascertained that some plant viruses retain their infectivity for long periods in frozen tissue or sap, or in plant tissue frozen and slowly dried over calcium chloride. Such procedures, however, are not suitable for preserving some labile and certain other viruses. M. Hollings and R. A. Lelliot (*Plant Path.*, 9, No. 2, 63; 1960) have now described effective methods for the freeze-drying of a considerable number of viruses. The preservation of sap preparations of forty-six isolates of thirty-nine plant viruses by the rapid sublimation of water from frozen suspensions and subsequent storage under vacuum (freeze-drying) was investigated. Infective virus was recovered from preparations of all strains, except one of potato virus *A*, after freeze-drying and after storage during periods varying from four to eleven months. It appeared that the spherically shaped viruses studied lost little or no infectivity during freeze-drying, but that several of the rod-shaped viruses lost much of their infectivity. There was no evidence of further serious loss of infectivity in forty-five of the preparations during the storage period.

Lalor Grants and Awards for 1961

THE Lalor Foundation has announced the programme of awards for 1961 which it is offering for support of research on the fundamental biochemical and physiological mechanisms concerned with fertility and the early stages of reproduction in various forms of life. The objectives are to further the knowledge and understanding of the basic phenomena involved and to extend and develop the possibilities for effective regulation and control. The awards may range up to 8,000 dollars a year, depending on the scope and duration of the project approved. Preference will be given to younger members of university and college faculty and staff, with an upper age limit of 41 years. The work may be carried on at the applicant's own institution or elsewhere. The Foundation will also grant post-doctorate summer or short-term research awards at the Marine Biological Laboratory at Woods Hole, Mass., or elsewhere for appropriate projects in the fields specified. For these awards, the stipends will normally not exceed 1,000 dollars for a single man or a woman, 1,200 dollars for a married man working at his home institution, and 1,350 dollars for a married man with principal programme at another institution. A number of these awards may be granted to nationals other than citizens of the United States, usually under the condition that the award holder's work shall be conducted at an American institution. Applications and inquiries should be sent to the Lalor Foundation, 4400 Lancaster Pike, Wilmington 5, Delaware, and applications must be received by January 16, 1961.

Non-Destructive Testing of Materials

THE British Council is organizing a course on the non-destructive testing of materials in London for two weeks beginning October 16. The course is designed for overseas industrial technologists and scientific research workers. Its aim is to provide them with a broad survey of work in progress in the United Kingdom on the development of non-destructive testing techniques and the uses to which these techniques are being put by industry. The course will consist of lectures, discussions and visits. The main emphasis will be on the scientific background. The inclusive fee for this course, which is residential, will be £47. Further information can be obtained from Miss B. Sinclair, The British Council, 65 Davies Street, London, W.1.

The Leopoldina German Academy of Sciences : Elections

THE Deutsche Akademie der Naturforscher Leopoldina, Halle, recently elected the following new members, among others, in the sections indicated: *Physics*, Prof. Hans Kopfermann (Heidelberg); *Geophysics*, Prof. Alfred Ehmert (Göttingen); *Chemistry*, Prof. Horst Böhme (Marburg), Prof. Harry J. Emeléus (Cambridge), Prof. Gunnar Hägg (Uppsala), Prof. Karl Myrbäck (Stockholm), Prof. Linus Pauling (Pasadena), Prof. Tadeusz Urbański (Warsaw), Prof. K. Venkataraman (Poona); *Botany*, Prof. Rudolf Mansfeld (Gatersleben).

The Night Sky in October

FULL moon occurs on Oct. 4d. 22h. 17m. U.T., and new moon on Oct. 20d. 12h. 03m. The following conjunctions with the Moon take place: Oct. 9d. 09h., Aldebaran 0·3° S.; Oct. 11d. 22h., Mars 5° N.; Oct. 22d. 21h., Venus 6° S.; Oct. 24d. 22h., Jupiter 5° S.; Oct. 25d. 21h., Saturn 4° S. In addition to these conjunctions with the Moon, Venus is in conjunction with Antares on Oct. 28d. 20h., Venus being 3° N. Mercury and Venus are too close to the Sun for observation. Mars rises at 21h. 15m., 20h. 50m. and 20h. 10m. at the beginning, middle and end of the month, respectively. It is in Gemini, and is a very prominent object, of magnitude + 0·1 on October 15, when its distance from the Earth is 88 million miles. Jupiter sets at 20h. 50m., 20h. 05m. and 19h. 15m. on October 1, 15 and 31, respectively. It is in Sagittarius, and may be seen low in the southwest after sunset, but conditions are not favourable for observation. Saturn is in Sagittarius, east of Jupiter, and sets at 22h. 00m., 21h. 10m. and 20h. 15m. at the beginning, middle and end of the month, respectively. Its stellar magnitude is + 0·7 and its distance from the Earth on October 15 is 940 million miles. There is one occultation of a star brighter than magnitude 6 visible at Greenwich: Oct. 9d. 0h. 24.9m., γ Tau. (*D*); Oct. 9d. 1h. 41·7m., γ Tau. (*R*). *D* and *R* refer to disappearance and reappearance, respectively. The Giacobinids are active on October 9, but conditions are unfavourable, and little activity is expected. The Orionids are active during the third week of the month, conditions being favourable; the radiant is near R.A. + 6h. 24m., Dec. +15°.

Announcements

DR. G. JONES, of the Rowett Research Institute, Bucksburn, Aberdeen, has been appointed to hold the Sophie Fricke Royal Society Research Fellowship in the Rockefeller Institute for the academic year 1960–61. Dr. Jones will leave the United Kingdom in October for the Rockefeller Institute, where he will be working on the fractionation and characterization of leaf proteins.

SIR WILLIAM SLATER, until recently secretary of the Agricultural Research Council, has been appointed chairman of the governing body of the Glasshouse Crops Research Institute in succession to Mr. T. Ainslie Robertson.

MR. V. CORY, at present deputy county advisory officer in the National Agricultural Advisory Service, Essex, has been appointed county advisory officer for Yorkshire (West Riding) in succession to Mr. J. Gibbons, who has been appointed county advisory officer for Somerset. Mr. Cory will take up his new post on October 3.

THE Association of British Chemical Manufacturers, 86 Strand, London, W.C.2, has published a booklet entitled "Chemical Plant Instrumentation. Some Notes on the Use of Measuring Instruments" (6*s*. to members; 7*s*. 6*d*. to non-members, post paid). The nine topics covered in some fifty pages include temperature and pressure measurement, gas chromatography, continuous gas analysis by infra-red, glass electrode *p*H-meter and smoke-density meters. The information will be of interest to the managements of industrial firms.

THE Institute of Physics and the Physical Society is arranging a conference on statistical mechanics (with special reference to irreversibility), to be held at Queen Mary College, London, on December 19 and 20. Further information can be obtained from the Secretary, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

THE annual meeting of the Physical Chemistry Society of France will be held at l'Hotel du Col de Voza, Chamonix-Mont Blanc (Haute Savoie), during June 26–30, 1961. The subject of the meeting will be "The Structure, Synthesis and Function of Deoxyribonucleic Acid". Further information can be obtained from the Secretary, Société de Chimie Physique, 10 Rue Vauquelin, Paris V^e.

THE AGARD Avionics Panel has arranged a symposium on "Radio Navigation" in conjunction with the Tenth AGARD General Assembly during October 3–9 in Istanbul. The proceedings will cover general problems concerned with navigation, including papers on wave-propagation, radio-navigation including Doppler and air-traffic control, space and astro-navigation and display methods and automatic approach and landing. Further information can be obtained from the Advisory Group for Aeronautical Research and Development, Organisation du Traité de l'Atlantique Nord, 64 rue de Varenne, Paris 7ème.

ERRATUM. Writing in connexion with the communication entitled "Staining for Iodine in Chromatograms of Human Plasma" in *Nature* of August 20, p. 691, Dr. J. D. H. Slater states that the limit of sensitivity quoted as 0·2 μgm./100 ml. should have been 2·0 μgm./100 ml. (line 19, p. 692). The authors have since developed a considerably more sensitive technique.

THE CHEMISTRY OF NATURAL PRODUCTS

IN the Great Hall of the University of Sydney on August 25 Sir Kenneth Street, Lieutenant-Governor of New South Wales, formally closed the ten-day Symposium, entitled "The Chemistry of Natural Products", which had been opened on August 15 by Sir John Eccles, president of the Australian Academy of Science, in the Wilson Hall of the University of Melbourne. The meeting had made history as the first outside Europe and North America to be sponsored by the International Union of Pure and Applied Chemistry. Some 150 chemists from 33 countries, together with more than 200 Australians, attended as registered members. From overseas, Prof. A. Stoll (Switzerland), past president of the International Union of Pure and Applied Chemistry, represented the present president, Prof. W. A. Noyes, jun. The United Kingdom delegates were led by two Nobel laureates, Sir Alexander Todd and Sir Robert Robinson. Prof. R. Kuhn, also a Nobel laureate, due to arrive from Heidelberg, was unfortunately absent through illness.

The Symposium has differed from those hitherto held in other countries in that it was not located only in one city. It began in Melbourne in the State of Victoria, where it remained during August 15–18, then migrated about 300 miles to Canberra in the Australian Capital Territory, and finally shifted another 200 miles to Sydney; these movements all being made by air.

The Symposium was organized by the Australian Academy of Science, and the choice of subject was logical because the investigation of the constituents of Australian plants has formed the longest continuing organo-botanical-chemical research endeavour of scientists in Australia during the past century. In a sense its origin can be said to lie with Dr. John White, surgeon-general to the 'first settlement', who—soon after 1788—ran out of English peppermint oil, and discovered that an efficient substitute could be obtained by distillation of the leaves of the eucalyptus growing around Sydney Harbour. Prof. John Read (one-time professor of organic chemistry in the University of Sydney) devoted a whole chapter of his "Humour and Humanism in Chemistry" to this and subsequent periods under the title: "Chemistry Reaches the Australian Bush". Half a century ago the pioneering investigations of Smith and Baker (in what is now the Sydney Museum of Applied Arts and Sciences), followed later by those of Read himself, and Penfold (for many years director of the Museum) and others, have given Australia a significant place in essential oil and terpene research.

Alkaloids were first extracted from Australian sources in 1861. Shortage of certain drugs during the Second World War, and the problem of stock poisons occurring in plant foods, have caused a more intensive and systematic examination of Australian flora, and have led to the setting up of a phytochemical survey; this has stimulated much research in university and government laboratories, and brought to light many novel colouring matters, glycosides, alkaloids, toxic or pharmacologically active compounds, etc., which were reported during the Symposium.

The scientific proceedings were divided into four sections, namely: (*A*) Aliphatic and Homocyclic Chemistry; (*H*) Heterocyclic Chemistry; (*B*) Biological Chemistry; and (*P*) Physical Methods. Owing to the large number of papers submitted, the first three sections unfortunately (for the chemists interested) ran as concurrent sessions. Pillars in the construction of the programme were 14 lectures, attended by the whole assembly. At the opening ceremony, Prof. A. Stoll (Switzerland) spoke on "Impact of Studies of Natural Products on Chemical Industry". Three symposium lectures were delivered as follows: Section *A*, Prof. F. Šorm (Czechoslovakia), "Terpenic Compounds with Medium-Sized Rings"; Section *H*, Prof. R. B. Woodward (United States), "The Total Synthesis of Chlorophyll"; and Section *P*, Dr. H. W. Thompson (United Kingdom), "Physico-Chemical Methods of Studying Natural Products". Prof. Kuhn's eagerly awaited "Chemistry of the Gangliosides" had perforce to be omitted. Eight section lectures, also attended by all delegates, were: Section *A*, Prof. D. H. R. Barton (United Kingdom), "Some Aspects of Terpenoid and Steroid Chemistry", and Prof. N. A. Sørensen (Norway), "Structural Patterns of Polyacetylenic Compounds isolated from the Plant Family Compositae"; Section *H*, Prof. H. Brockmann (West Germany), "Chemistry of the Actinomycins", and Prof. T. R. Govindachari (India), "Recent Investigations on Some Alkaloids from Indian Plants"; Section *B*, Dr. J. W. Cornforth (United Kingdom), "The Biosynthesis of Polyisoprenoids", and Prof. E. Lederer (France), "Chemistry and Biochemistry of Biologically Active Bacterial Lipids"; Section *P*, Prof. C. Djerassi (United States), "Application of Optical Rotatory Dispersion Studies to Problems in Natural Products Chemistry", and Dr. A. McL. Mathieson (Australia), "The Direct Determination of the Molecular Structure of Natural Products". Dr. J. R. Price (Australia) gave a special lecture entitled "Australian Natural Product Research".

Sir Alexander Todd, as president of the Symposium, gave as his presidential address in the new Academy headquarters in Canberra a general review, coupled with a plea that biochemistry must bridge biology and organic chemistry, by studies of function and structure, if it is to make its most successful contribution to knowledge. He spoke on "Natural Product Chemistry—Retrospect and Prospect".

Sir Robert Robinson summed up the scientific achievements of the Symposium at its closing ceremony. He said: "It would be presumptuous for me, or anyone else for that matter, to pretend to be able to perform adequately the task which I must now attempt. For one thing, none of us has been able, as we might have wished, to be in three places at the same time. Furthermore, the printed abstracts are largely of the nature of appetizers, an invitation to the lunch, but with a masterly reticence with regard to the menu, to say nothing of the details of the cooking". . . . "For me it has been throughout an entrancing and spectacular display of progress and promises of future advances". Sir Robert specifically referred to Dr. Thompson's lecture, saying that although Thompson himself was a pioneer of infra-red spectroscopy he "gave pride of place to X-ray crystallography, because this method 'gives full structural information—not only that, but also solves the stereochemical problems". Sir Robert proceeded to note the part taken by Djerassi's work on optical rotatory dispersion, by mass spectrometry and by nuclear magnetic resonance, as well as by infra-red and ultra-violet spectra, in the discussions and lectures of the Symposium. He warned, however, that the classical organic chemist is certainly not to be displaced by machines . . . there is no need to discuss whether an absorption band is due to N—H or O—H if the compound does not contain nitrogen. "even if we know the structure we still have to explore the surrounding chemical territory . . . would it be good for organic chemistry as a whole if the structure of indigo had been solved by looking at a few milligrams of it, and if Baeyer had not carried out any of his wonderful work which led to the determination of its formula ? I think not !"

He went on: "We were greatly privileged to hear the lecture by Prof. R. B. Woodward, in which he described, I believe for the first time, the outstanding achievement of the total synthesis of chlorophyll. Prof. Woodward is not only a most brilliant synthetic organic chemist, but also an expositor, able to convey a sense of the drama of development to his audience. His lecture was thoroughly enjoyable, even thrilling as an experience. No doubt in places he admitted to a little good fortune, but he also made it clear it was expected. I was reminded of Benjamin Franklin's 'Luck is the bonus that accrues to industry'. Woodward and his team were surely industrious".

"This achievement of the synthesis of chlorophyll is a very good example of the kind of thing which one is often asked about . . . What good is it ? Of course, the good that it is, is the new knowledge which is obtained . . . the new knowledge of the behaviour of chlorophyll, the nature of the molecule, how it is likely to behave in other circumstances. . . . That new knowledge may lead us we don't know where".

About Prof. Lederer's lecture Sir Robert said: "It was quite outstanding in interest and importance. I had no means for measuring decibels of applause or its duration, but it was clear my assessment was widely shared. Lederer described extensive studies on biologically active bacterial lipids. . . . He explained in full the problems which had been finally solved, and even more useful, he indicated the stages reached in the solution of others, including some which may have great significance for the therapy of tuberculosis in the future. Lederer's mastery and humorous style charmed us. His contribution will certainly be remembered".

He continued: "Another aspect which has been running through the Symposium is that of biogenesis and structural relations, and the use of isotopic tracers to test the various hypotheses advanced in this connexion. . . . I think the lecture by Dr. J. W. Cornforth was an extremely important event in the conference—one of the real highlights. The way in which Cornforth was able to describe the complete story for the synthesis of poly*iso*prenoids was quite remarkable. It was . . . a lecture of great value to all of us".

Sir Robert then referred in terms of praise to all the other lectures mentioned above, to the "infectious enthusiasm" of Erdtman, the "brilliance" of Barton, Šorm and Brockmann, the many valuable and novel facts presented by Sørensen, Govindachari and Mathieson, impossible to summarize in the detail they deserve. Concerning Prof. Stoll's review of the impacts which natural product research has on industry, Sir Robert said: "These reverberations are important . . . Stoll's work is as academic as anyone else's . . . he has made extraordinarily valuable and neat contributions to the chemistry, for example, of the digitalis and ergot series". These have not been without profit in all senses of the word. Sir Robert paid a tribute to the survey of past and present Australian work by Dr. Price in his special lecture, and to the results presented by Price and collaborators in papers to Sections *H* and *P*. These, he said, showed how many opportunities exist in Australia for natural product research, and how beneficial has been the guidance of Dr. Price and his associates in the laboratories of the Commonwealth Scientific and Industrial Research Organization.

Sir Robert concluded: "Possibly the outstanding scientific value of the Symposium has been the opportunity it has afforded for the meeting of colleagues from all over the world for discussions . . . not only in the lecture theatres, but also in other places where we meet and talk together. . . . It has been the most outstandingly successful symposium I personally have ever taken any part in. I have never experienced a symposium in which so many papers of the greatest possible interest have been delivered . . . and I must say that I think it is due to the enthusiastic coming together of organic and physical chemists in the past twenty years, from which union we have gained advantages of powerful procedures . . . of chromatography, ordinary and vapour phase, of micro methods of analysis and of manipulation, of the many physical ways of examining products, of the availability of isotopes, and the techniques for handling them, and from which we can still see further new methods developing on the horizon . . . all this has made the Symposium a most significant occasion. We hope to repeat it in Czechoslovakia in 1962".

Sir Robert then spoke with appreciation of Sir Alexander Todd's services as president of the Symposium—this was received with great applause—and the meeting was closed by Sir Kenneth Street.

Officially the planners received strong support in high places. His Excellency the Governor-General of Australia, Viscount Dunrossil, was patron-in-chief, and Their Excellencies the Governors of New South Wales and of Victoria were patrons.

Official receptions were given by the Premiers of Victoria and New South Wales in Melbourne and Sydney respectively, and by the Prime Minister in Canberra. Immediately prior to the opening, Sir Alexander Todd received the honorary degree of doctor of laws from the University of Melbourne, and on August 24 the University of Sydney conferred on Sir Robert Robinson (first professor of organic chemistry in Sydney) its D.Sc. (*honoris causa*).

A full programme of social events and excursions for members and their ladies was also carried through. Outstanding were the Government receptions, the banquet in Canberra, a 'wine and cheese tasting' in Sydney by courtesy of the Australian Wine Producers' Association of New South Wales, and a fashion parade in Melbourne of Australian woollens, arranged by the Australian Wool Board. The last two, together with the many scenic tours possible from the three centres, proved of great interest to visitors who had not previously seen the Australian way and place of life. Post-Symposium tours to north and south Queensland and to New Guinea are now in progress—the last-named being for men only and at the invitation of the Commonwealth Government and the New Guinea Administration.

The lectures mentioned above will be published through the Publications Committee of the International Union of Pure and Applied Chemistry by Butterworth's Scientific Publications, London.

R. J. W. LE FÈVRE

WARREN SPRING LABORATORY

IN planning the Warren Spring Laboratory at Stevenage, the Council for Scientific and Industrial Research decided that it should be a versatile station free to carry out research which cannot be fitted into the programme of another research body, especially work involving pilot-scale investigations of any subject of national importance.

As a result, the Laboratory's research programme includes a number of important investigations in several different fields[*].

In chemical engineering, for example, the work is concerned mainly with providing the chemical plant designer with basic information. Considerably more knowledge is required to achieve greater precision in design work. The basic programme is confined to the study of mass transfer in gas–liquid systems, and these investigations will provide data for the precise design of large-scale equipment without the need for costly pilot-plant studies. For example, the investigation should enable more accurate prediction of the performance of gas–liquid contacting equipment to be made and thus facilitate the design of equipment such as distillation columns and gas absorption towers.

Much of the work of the Mineral Processing Division is undertaken for mining companies and other organizations, on repayment. Three main subjects of basic research are being studied: (*a*) grinding in the presence of additives such as surface-active agents; (*b*) the composition of surface minerals and the kinetics of bubble attachment to mineral surfaces; (*c*) the behaviour of mineral particles in a high-tension field and the modifications of this behaviour by various surface treatments. There have been indications during the year that automation may become important in mineral processing plants and an experimental programme is being considered.

In the Process Development Department, work has continued on the Fischer–Tropsch synthesis, which provides a method of obtaining liquid and gaseous fuels from carbon monoxide and hydrogen, which are produced by the complete gasification of low-grade high-ash coal. Basic research on catalysis has included work on the catalytic and other physico-chemical aspects of fuel cell operation.

A small human sciences research team is being formed at the Laboratory, and the Human Sciences Research Sub-committee, under the chairmanship of Mr. H. Briggs, labour adviser to Unilever, Ltd., is now considering the programmes of research in this increasingly important field.

Current research into air pollution concerns both methods of abatement and assessment of atmospheric pollution throughout Britain, with relation to the effects of clean air legislation. Estimates made during the year have shown that, in general, smoke from the burning of industrial coal has ceased to be a serious problem although in some instances it creates a local nuisance. The Laboratory has co-operated with the Port of London Authority and owners of tugs in demonstrating methods of reducing smoke emission from ships in coastal waters.

Smoke from Diesel exhausts provides another research problem. While a well-maintained and correctly operated Diesel vehicle need never produce black smoke, the fact remains that large numbers of lorries frequently do. Methods of removing smoke from exhaust gases are being studied. A 10-ton Diesel lorry fitted for road tests with various proprietary devices is being used for this purpose.

The Laboratory has continued to collaborate with local authorities on the measurement of pollution, and this is providing "a wealth of background information against which future improvements can be assessed".

Methods of measuring low concentrations of oxides of nitrogen (known to be emitted by practically all fuel-burning appliances) are being examined. These emissions may be significant factors in air pollution.

U.K. ATOMIC ENERGY AUTHORITY

THE sixth annual report of the Atomic Energy Authority, the first to appear over Sir Roger Makin's signature and also the first to be submitted to the Minister for Science, covers the period April 1, 1959–March 31, 1960[*]. During that year, those major projects undertaken primarily to support the defence programme were completed, and all main plants constructed for that purpose were operating successfully. New capital projects approved during the year were on a relatively small scale. The Authority continued to devote a major effort in support of the civil power programme of the Central Electricity Generating Board and the South of Scotland Electricity Board. The report includes as an appendix the observations of the Minister for Science, in consultation with the Authority, on the fifth report of the Select Committee on Estimates on the Authority's Industrial Group. These comments have now been transmitted to the Committee.

---

[*] United Kingdom Atomic Energy Authority. Sixth Annual Report for the period 1st April, 1959–31st March, 1960. Pp. vi+72+4 plates. (London: H.M. Stationery Office, 1960.) 5*s*. net.

Generally, the Authority welcomes the report and has accepted and will implement most of its recommendations. On the remaining recommendations, it is commented that the Authority has reviewed its budgeting procedure and taken steps to ensure that the original factory and laboratory estimates are prepared on as broad a basis as possible and contain no more detail than is essential to ensure the build-up of a realistic total. The Authority agrees with the Committee's view of the importance of taking account of long-term effects, both in staff and further capital expenditure, of current proposals, and will include in any application for sanction of a capital project connected with the development of a new reactor system a rough forecast of expenditure which may be necessary in the foreseeable future as a consequence of the particular capital project for which sanction is requested. The Authority also accepts that the Treasury should be informed of the contingency margin allowed in project estimates for experimental facilities for which it is impossible to give precise detailed specifications at the outset, and the Treasury will also be informed at the next stage of estimating what margin has been retained as a working margin. The Authority also accepts the general intention of the recommendation that it should be standard practice to allow design officers sufficient time to go out to tender for all major components of large civil reactor and plant projects, and fully endorses the Committee's statement that "the future course of the nuclear power programme will be directly affected by the availability or otherwise of the fast reactor in the early 1970's, which means that its value must be established by about 1966". The fast reactor is regarded as an integral part of the nuclear power programme and the Authority will press on with its development as rapidly as possible: it is already receiving, and will continue to receive, full technical support.

On the financial side it must be observed that the balance sheet appended to the report still gives no indication as to the way in which the £92,433,010 of the 1959–60 estimates were expended. The sixth report, like its predecessors, gives no indication whatever of the magnitude of our effort in research on nuclear energy or of the cost of the nuclear power programme, either as a whole or in the development of reactors. Indeed, even less information is available than was to be found in some earlier reports, though it is stated that early in 1959 the Authority decided to limit the growth of man-power on research and development for the next three years to an annual rate of not more than 8 per cent. Within this rate of expansion, recruitment in general has been satisfactory, although difficulty is still experienced in recruiting engineers and scientists of sufficient experience and calibre for higher management posts, and in obtaining scientific and professional staff in particular disciplines in which there is a national shortage. The total staff employed increased from 35,260 on April 1, 1959, to 38,500 on March 31, 1960, industrial employees increasing from 18,217 to 19,572.

On the production side the report records an increase of 40 per cent in the output of fissile material and of 300 per cent in that of electricity, while most of the teething troubles of the full-scale prototype unit for converting uranium nitrate into tetrafluoride, using fluidization techniques, have been overcome, and the plant is operating as a production unit yielding uranium tetrafluoride of good quality at the design throughput. Satisfactory progress is also recorded in the reactor development programme, and stress is laid on the importance of reductions in capital costs if nuclear power is to be competitive not only at base load but also at the lower load factors at which nuclear power stations will have to operate when substantial nuclear capacity has been built. This largely depends on the development of more advanced reactors, and here a large effort has been devoted to the support of the 'magnox' stations, particularly the development of fuel elements to provide good performance with reliability. Progress in the advanced gas-cooled reactor system has been encouraging: the system should be capable of lower capital costs than 'magnox' stations and its prospects are good. Development of the fast reactor proceeded steadily, and the experimental reactor at Dounreay came into operation at low power. Most of the staff working on the high-temperature gas-cooled reactor system were seconded to the *Dragon* project, under the auspices of the Organization for European Economic Co-operation. Other work on reactors included investigations into the design of a steam-cooled heavy-water reactor and its variant, the steam generating heavy-water reactor.

The wide range of the Authority's research activities is displayed in the chapter on general research and development. In nuclear physics, for example, a major group of work is concerned with the behaviour of nucleons when they collide in free space, uncomplicated by the proximity of other nucleons as in nucleon–nuclear reactions. The cyclotron has also been used to investigate the interaction of a high-energy nucleon with a nucleus and the interactions between nucleons and nuclei have also been studied at fairly low energies, using the 5-MV. Van de Graaff generator and newly completed 12-MV. tandem electrostatic accelerator at Harwell. A new particle detector has been developed in which a p–n junction in a semiconductor, such as silicon or germanium, is used as a solid-state ion chamber to produce an electrical impulse when a nuclear particle traverses the junction, and also a large heavily shielded liquid scintillation counter for work on neutron emission in fission. In solid-state physics a fundamental experiment has been carried out using lithium isotopes, and a change of thermal resistance with isotope concentrations was observed in measurements at Capenhurst of the thermal conductivity of single crystals of lithium fluoride containing lithium-6 and lithium-7 in the temperature range 10°–90° K. In radiation chemistry much work has been undertaken in connexion with the problems of radiation change in reactors and in fuel processing plants. For example, work on the γ-radiolysis of methyl acetate has shown how complicated the degradation of a simple ester can be, and work on the radiolysis of trialkyl phosphates showed that, in addition to hydrogen and light hydrocarbons, dialkyl and smaller amounts of mono-alkyl phosphoric acids are produced. The behaviour of the system carbon dioxide/carbon monoxide/graphite under irradiation has been studied to determine the basic parameters that affect the rates of the reactions, and the influence of geometrical factors on the radiation-induced reaction producing carbon monoxide is being studied in sealed tubes. Another investigation was concerned with the nature and properties of radioactive aerosols, and laboratory experiments have been made on the release of iodine in air and carbon dioxide at very low vapour concentrations. Considerable technical work has been undertaken into criticality to back particular design studies as well as a more generalized study.

Work continued on the application of radioisotopes, especially in industry. The method of fluorescence spectroscopy, using radioactive sources, has been applied to measuring very thin surface coatings, and by tracer methods the rate of flow of liquid in closed channels can now be measured with an error of less than one part in 200. Further work has been done on the use of large sources of γ-radiation for sterilization and other purposes, and a pilot-scale plant for irradiating packages of materials with γ-rays has been built at Wantage. A mass spectrometer has been developed at Capenhurst for the analysis of the active species present in gas/solid chemical reactions, and basic studies have been made of the friction and wear behaviour of materials in reactor coolant environments at high temperatures. Considerable progress has been achieved at Aldermaston in the provision of short-duration radiographs of systems opaque to ordinary light and moving at high speed, and two types of mechanical very-high-speed cameras are manufactured at Aldermaston, one, the streak camera recording along a length of film the size of a light source which is varying with time, the other, the framing camera, producing individual pictures at intervals on a strip of film. A third type takes a single picture with a time of exposure of 1×10^{-7} sec., using a Kerr cell shutter.

In the work on controlled thermonuclear reactions, the stored energy supply and the stabilizing magnetic field supply of *Zeta* were both increased by about six times during the year, and experimental elucidation of the physical phenomena in the *Zeta* and *Sceptre* plasmas continued successfully, while work also continued on some other plasma physics problems, and considerable progress was made in solving the formidable technological problems associated with the production and control of currents in the range of 10^4 amp., and in the development of methods of construction to withstand the severe conditions expected in experiments such as the Intermediate Current Stability Experiment. The Authority has reconsidered its earlier decision to move controlled thermonuclear research from Harwell to Winfrith, and has chosen instead a site at Culham, where the laboratories to be erected will form a large autonomous unit within the Authority's Research Group. The Authority's commitments under its long-term uranium contracts are now greater than its immediate requirements, and for some years, mainly due to the slowing down of the nuclear power programme, it will hold larger uranium stocks than it needs. A new Health and Safety Branch, independent of the Groups, was established as from July 1, 1959, to advise on the formulation of health and safety policy and disseminate this policy for application by heads of groups and establishments, apply this policy to the assessment and inspection of reactors and plant, and provide the focal point for conducting external relations in this field. A wide range of health and safety problems investigated during the year included developments in measuring techniques applied to the monitoring of fall-out from nuclear weapon tests, controlled studies of the uptake from fresh water of strontium-90 by fish and of this and other radioisotopes by common aquatic plants, and work on the diffusion and dispersion of gases and particulates.

Information Services have included, besides the Harwell Reactor School, the Calder Operation School, the Isotope School, now at Wantage, and the training programme for Central Electricity Generating Board operating staff, the issue of an illustrated summary of this sixth annual report, together with some additional material to July 1, 1960*.

TUBERCULOSIS: RISK TO FAMILY CONTACTS

In developed countries with adequate hospital accommodation, drug treatment of tuberculosis has often freed beds. In less-developed countries with inadequate hospital accommodation, the problem of beds for tuberculous patients remains acute. In India, for example, it is particularly serious, since there are only 23,000 beds for tuberculous patients, against a total number of persons affected that may be put at between 1·5 and 2·5 million. Because of this, a comparative study of domiciliary and sanatorium treatment of tuberculosis was undertaken by the Tuberculosis Chemotherapy Centre, Madras, which was set up in 1956 under the joint auspices of the World Health Organization, the Indian Council of Medical Research, the Madras Government and the Medical Research Council of Great Britain. The purpose of the study was to determine whether drug treatment of tuberculosis in a country like India was as effective in the home as in the sanatorium; or, to put it differently, whether domiciliary treatment did away with the need to send a fair number of tuberculosis patients to hospital (*World Health Org. Chron.*, 14, No. 7; July 1960).

A group of 193 patients were selected, most of them from the poorest classes of Madras City. They had to be more than twelve years old, to have had no previous drug treatment, and to have a positive sputum. Out of these 193 patients, 96 were treated at home, 97 in the sanatorium. The period of comparison lasted a year, and the results of the study indicated that domiciliary treatment seemed to give as good results as sanatorium treatment.

There remains the important point whether the risk of infection to the family is not greater when the patient is treated at home. A fresh study was carried out under World Health Organization auspices on the same group of patients to determine the overall prevalence of cases of tuberculosis among family contacts when the diagnosis of tuberculosis was established in the family member included in the comparative study (the index case), and the number of fresh clinical and primary cases occurring among family contacts during the first year of his treatment. Contacts include all the other members of the family, but the inquiry was limited to 'close' family contacts, that is, those who had been living with the index case for at least three months before diagnosis. In fact, 96·7 per cent of the 693 close family contacts had been living with the index case for at least a year.

Examinations were carried out in 693 contacts of the 193 patients treated at home or in the sanatorium; of these, 347 were men and 346 women. The survey of the prevalence of tuberculosis when the index case started treatment was based on 672 contacts. Active tuberculosis was found in 46; in another 2, activity was doubtful; and in 11, tuberculosis was inactive.

Of still more interest was the inquiry into fresh cases of tuberculosis appearing in close family contacts of patients treated either at home or in the sanatorium during the first year of treatment. There were 257 contacts of the 75 patients treated at home, and 275 contacts of the 73 patients in the sanatorium. The two groups were alike in the proportion of men to women, in the kind of home they lived in and in the results of the initial examination; and they were followed up in the same way during the year of the inquiry. During this year, 26 active cases of tuberculosis were discovered in the two groups of contacts; 9 (3·5 per cent) in the group of contacts of patients treated at home, and 17 (6·2 per cent) in the group of contacts of patients treated in the sanatorium.

Of these 26 cases, 15 were less than five years old and 21 less than two years old. The most serious cases all belonged to the group whose index cases were treated in the sanatorium.

Even if encouraging conclusions can be drawn from this study, domiciliary treatment of the open tuberculous patients should be considered an emergency measure only, to be taken when institutional treatment for 3–6 months is impossible because of shortage of beds. Every effort should be made not to send patients home until their sputum has become negative for tubercle bacilli, at least on microscopical examination.

A final conclusion is that the frequency and seriousness of tuberculosis lesions in young contacts are a sufficient justification for systematic prophylactic treatment of children whenever a sputum-positive patient is newly diagnosed in their household. This treatment should be started immediately and carried out for a minimum period of six months.

NOISE IN FACTORIES AND ITS CONTROL

NOISE is always associated with the application of power, and the trend towards the use of more powerful machines in industry is making the problem of noise in factories increasingly serious. A survey "Noise in Factories", by A. G. Aldersey-Williams, which has recently been published for the Department of Scientific and Industrial Research (Building Research Station) in the series "Factory Building Studies" (No. 6. Pp. iv+26. London: H.M. Stationery Office, 1960. *3s. 6d.* net), emphasizes that the noise factor should be considered at the earliest stages in the planning of a factory. Choice of the manufacturing method, which largely determines the noise-level and its effect on the occupants of the factory and residents in the area, is the responsibility of the management. Noise at source can be reduced by machine manufacturers in the design of their machines, but where this is not possible, factory engineers can minimize the effect by taking precautions in the installation of the machines, and the building designer can reduce annoyance by siting noisy equipment away from other buildings and by the use of enclosures and sound-absorbing roof linings.

The 26-page booklet consists of two parts. Part 1 deals with the properties of sound and explains the terms used, the sources of noise in factories, and the effects of noise. It is pointed out that the most intense noise in factories is generally caused by machine tools and by operations involved in making and handling the product, and it is only when the process is a quiet one that the noise from service equipment, such as fans, pumps and compressors, may be the more intense. Excessive noise will influence the welfare, safety and, indirectly, the efficiency of the occupants of the factory. As the level of noise increases, its effect on people is first annoyance, then interference with communication and, finally, damage to hearing. In addition, since noise is associated with vibration, the performance of delicate equipment in the factory may be upset, and if the noise is transmitted through the factory structure or through the ground to the outside of the factory, it may also cause discomfort.

In Part 2, methods for the reduction of noise and their effectiveness are discussed. The radiation of noise, resonance and damping, and vibration isolation are dealt with first, then noise reduction and lay-out, enclosures to reduce noise, sound-absorbing materials, partial enclosures and screens, and finally ear protection. The most effective way of controlling noise once it has been generated and radiated is to contain it within an enclosure, a reduction of about 50 db. being readily provided by an ordinary building enclosure; but the efficiency of an enclosure depends on its completeness and uniformity, and direct air leaks through a hole or through porous material reduce the efficiency considerably. The build-up of reverberant sound within an enclosure can be controlled by the use of sound-absorbing materials to reduce the amount of sound reflected. The booklet gives a list of absorption coefficients of common sound-absorbing materials and contains illustrations of various sound-absorbing arrangements in factories. For individual ear protection, where operators of noisy machines are exposed to high levels of noise, two forms of commercially available 'ear defenders' are ear plugs and ear muffs. Ear plugs are inexpensive, small and inconspicuous, but may be uncomfortable when first worn. Dry cotton wool is not an effective ear plug. Ear muffs fit over the ears, and though heavier and more expensive than ear plugs, they give greater reduction of noise. In the latest types the seal around the ear is made by a plastic cushion partly filled with liquid, and the muff is very comfortable to wear even for long periods of time.

S. Weintroub

PENETRATION OF CHARGED PARTICLES IN MATTER

DURING September 15–18, 1958, an informal conference was held at Gatlinburg, Tennessee, to discuss the penetration of charged particles in matter. Penetration of Charged Particles in Matter: Proceedings of an Informal Conference, Gatlinburg, Tennessee, September 15–18, 1958. Edited by A. Vehling. (Nuclear Science Series, Report No. 29. Publication No. 752.) Pp. x+174. (Washington, D.C.: National Academy of Sciences—National Research Council, 1960.) 2 dollars.) The conference, which was attended by about fifty scientists from Canada, Europe, Asia and the United States of America, was organized by the Sub-committee on Penetration of Charged Particles in Matter of the National Academy of Sciences—National Research Council and sponsored by the United States Atomic Energy Commission, National Science Foundation, and the Air Force Office of Scientific Research.

About twenty-five talks were given and the proceedings of the conference, edited by E. A. Vehling of the University of Washington, have now been published. Topics ranging from the reliability of experimental data to new approaches in the theoretical description of energy-loss mechanisms were discussed. The papers are presented under five headings: stopping power and range, recent developments in the theory of stopping power, charge-changing collisions, atomic and molecular scattering, ionization in gases by high-energy particles, and microscopic and macroscopic energy-loss distributions.

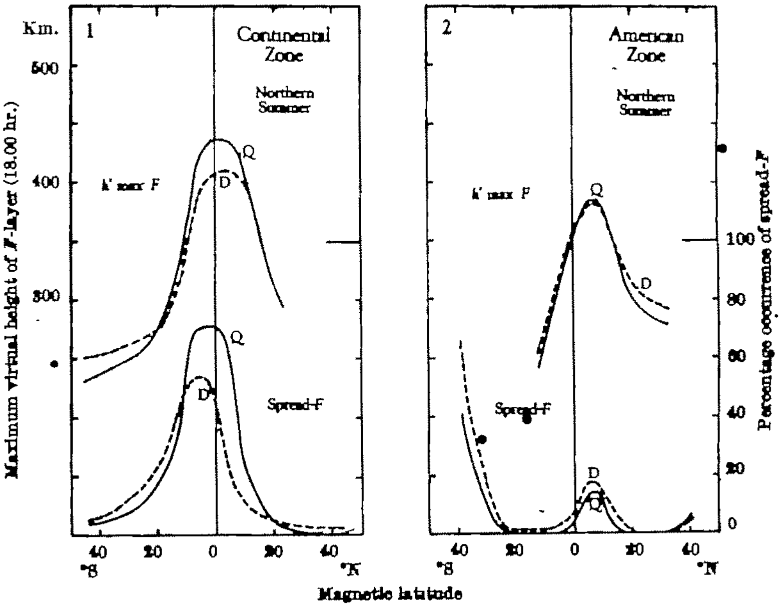
Prof. S. K. Allison, who introduced the papers on charge-changing collisions, discusses measurements on the formation of negative lithium ions, and C. Y. Fan explains briefly the spectroscopic study of electron-capture processes. U. Fano summarizes the various theoretical reviews given in the final section of the proceedings dealing with energy-loss distributions and adds an appendix in which he comments on 'collective' effects in atoms and in extended media. J. B. Hasted, of University College, London, the only representative from the United Kingdom, reports on coincidence methods of studying inelastic ionic collisions.

The articles have been prepared either by the speakers or by the chairmen of the various sessions in collaboration with the speakers. In some instances the reports include the results of the subsequent discussions. In a few cases the original reports have been shortened or reduced to abstract form because of publication of the full report elsewhere. References are given.

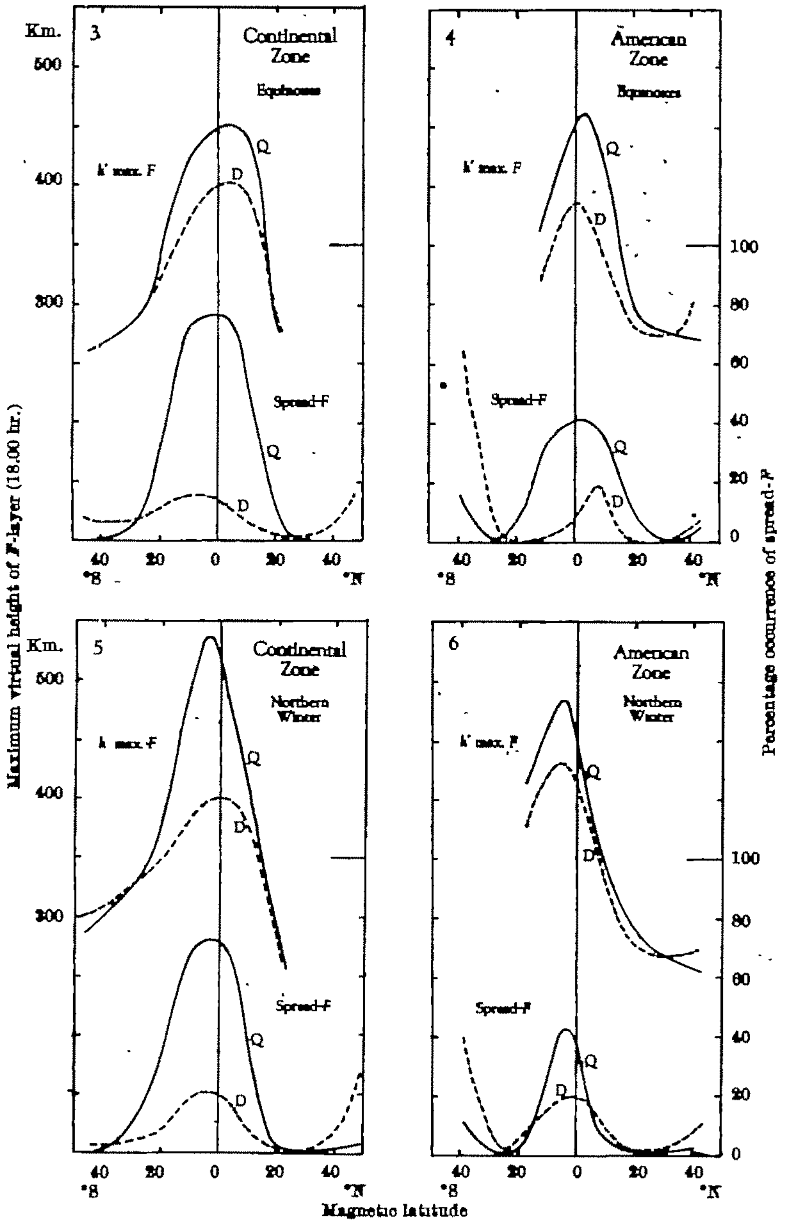
EQUATORIAL SPREAD-*F* AND *F*-LAYER HEIGHTS

By DR. A. J. LYON and DR. N. J. SKINNER
University College, Ibadan, Nigeria
AND
PROF. R. W. WRIGHT
University College of Ghana, Legon, Ghana

WE recently reported[1] on the surprising inverse correlation observed near the magnetic equator between the occurrence of spread-*F* echoes and magnetic disturbance, in contrast to the direct correlation observed at temperate latitudes. The evidence then presented related to the exceptionally disturbed month of September 1957, and was derived from observations at only a few ionospheric stations. We have now extended our analysis to cover a twelve-month period of the International Geophysical Year (November 1957–October 1958), and have used observations from about sixty stations distributed over a wide range of magnetic latitude. In addition we have made a parallel study of the rapid rise in the height of the equatorial *F*-layer which occurs just after local sunset (from about 300 km. to more than 400 km. in 1–2 hr.). It



Figs. 1 and 2



Figs. 3–6. Variations of $h'_{\max.}$ F, the maximum value of $h'F$ in the six hours after local sunset, and of the percentage occurrence of spread-F, both plotted against magnetic latitude, for magnetically quiet (Q) and magnetically disturbed (D) conditions

was noted many years ago[2,3] that this rise occurs just prior to the development of the spread-F condition.

The twelve months under review were divided into three 'seasons', and the stations were divided into two zones, the American zone and the 'Continental zone' comprising Europe, Africa, and Asia. The mean percentage frequency of the occurrence of spread-F at night, and the mean maximum virtual height ($h'_{\max.}$ F) reached by the F-layer in the early part of the night, were computed both for magnetically quiet and for magnetically disturbed conditions for all the stations. The spread-F index was derived mainly from published tables of f_0F_2, but was checked whenever possible by reference to the ionograms. The results of this analysis are summarized in Figs. 1–6. The upper curves refer to heights and the lower ones to the spread-F index in each case, and both parameters are plotted against magnetic latitude.

A number of conclusions may be drawn from these graphs.

(1) The equatorial belt, within which spread-F is a common occurrence under magnetically quiet conditions, extends from roughly 20° north to 20° south of the magnetic equator. The smaller incidence in the American zone is at least partly due to different conventions in scaling the data. There is probably little if any difference in the general incidence of spread-F between the hemispheres. Only in one case (northern summer, American zone, Fig. 2) is the belt substantially narrower.

(2) Within this belt there is in general a sharp diminution of spread-F during magnetic disturbance. (Again only American summer is exceptional.)

(3) The change-over to a direct correlation between spread-F and magnetic activity generally occurs at about 30° N. or 30° S. magnetic latitude.

(4) In the American zone there is a small seasonal movement (about ± 5°) of the maximum of the spread-F belt, but no corresponding movement has been detected in the other region.

(5) Comparison of the upper and lower curves in Figs. 1–6 shows that there is a remarkably close coincidence between the spread-F belt and the belt of steep post-sunset rise in $h'F$. The widths of the belts and the positions of the maxima agree very well; in particular, in the American zone the belt of rising $h'F$ follows exactly the seasonal movement of the spread-F belt. Moreover, the reduced spread-F incidence during magnetic disturbance corresponds to reduced rise of $h'F$ in every case. Perhaps most convincing of all, in the one exceptional case where there is no reduction in spread-F during magnetic disturbance (Fig. 2), there is also no reduction in the rise of $h'F$; and indeed in this case both the rise in $h'F$ and the spread-F incidence are the smallest.

The remarkable correlation between the occurrence of spread-F and the prior rise of height of the layer might be accounted for in terms of Martyn's theory[4], which ascribes the irregularities producing spread-F to upward vertical drift of ionization. Alternatively, it might be considered to support the theory of Dessler[5] that spread-F arises from hydromagnetic waves of extra-terrestrial origin propagated downwards and "channelled by refraction into the 400 km. level". The evidence of Figs. 1–6 might well suggest that a height of about 400 km. is critical for the formation of spread-F. However, neither theory appears to account satisfactorily for the fact that equatorial spread-F usually continues throughout the night, even although after about 20 hr. the height of the layer decreases and for much of the night is below 300 km.

The results summarized above will shortly be published in greater detail elsewhere.

A NEW LIMIT TO THE GALACTIC MAGNETIC FIELD SET BY MEASUREMENTS OF THE ZEEMAN SPLITTING OF THE HYDROGEN LINE

By DR. R. D. DAVIES, C. H. SLATER, W. L. H. SHUTER and P. A. T. WILD

Nuffield Radio Astronomy Laboratories, Jodrell Bank, University of Manchester

THE existence of a magnetic field in the Milky Way system has been inferred from the regularity in direction of polarization of the light from distant stars, from the isotropy of high-energy cosmic rays and the presence of galactic radio-frequency emission attributed to the synchrotron mechanism. However, none of these observations gives a direct measure of the magnitude of the galactic magnetic field; various estimates of the magnetic field in the galactic disk based on these data give values in the range $0{\cdot}5 \times 10^{-5}$ oersted to 3×10^{-5} oersted.

The Zeeman splitting of the line radiation from interstellar neutral hydrogen can be used as a technique for detecting weak interstellar fields. The line-of-sight component of the magnetic field gives rise to a splitting of the radiation into left- and right-hand circularly polarized components separated by 2·8 mc./s. per oersted. The effect is most readily measurable in the narrow deep absorption features in the spectra of the intense radio sources. A previous attempt to detect the field in this way gave an upper limit of 5×10^{-5} oersted[1]. The present article describes further experiments which set a new limit to this interstellar magnetic field.

The three deep lines in the Cassiopeia-*A* absorption spectrum were studied. One is caused by a cloud in the Orion arm and two by clouds in the Perseus arm. The narrow feature investigated in the Taurus-*A* spectrum is in the Orion arm and that in the Sagittarius-*A* spectrum is in the 3 kiloparsecs expanding arm. The positions of all the five clouds studied are indicated schematically in Fig. 1. The experiment was conducted in two parts; the Orion arm cloud and the 'near' Perseus arm cloud of the Cassiopeia-*A* spectrum were measured in the period March 6–22, 1960, while the three other clouds were investigated during May 26–June 7, 1960.

The experimental technique consisted of controlling the 250-ft. radio telescope to follow the required radio source and switching the receiver to accept left-hand and then right-hand circular polarization once every 24 sec. This polarization switching was effected by rotating a quarter-wave dielectric plate from one plane to the other of the square wave-guide section which illuminated the paraboloid. The receiver incorporated a phase-sensitive detector and would respond to any Zeeman splitting since this would produce a phase-sensitive component with a 24-sec. period. The half-power band-width used was 7 kc./s. in all measurements except those on the narrow feature in the Taurus-*A* spectrum, where it was 4 kc./s. A given absorption feature was then scanned in frequency using a variable second local oscillator. 60–100 such scans were taken on each of the five absorption lines.

Each of the absorption profiles was analysed for the presence of a magnetic field in the following way. About 40 of the best scans were added together to obtain a mean curve. If polarization were present this curve would have the shape of the differential of the absorption profile and for any given profile the amplitude of this expected curve would be directly proportional to the strength of the magnetic field. As an example, the mean curve and the absorption profile observed in the Orion arm cloud in the Cassiopeia-*A* spectrum are shown in Fig. 2. Each mean curve was then fitted by an expected curve the amplitude of which gave the least-squares deviation, and the magnetic field corresponding to this curve is given in column five of Table 1 together with the

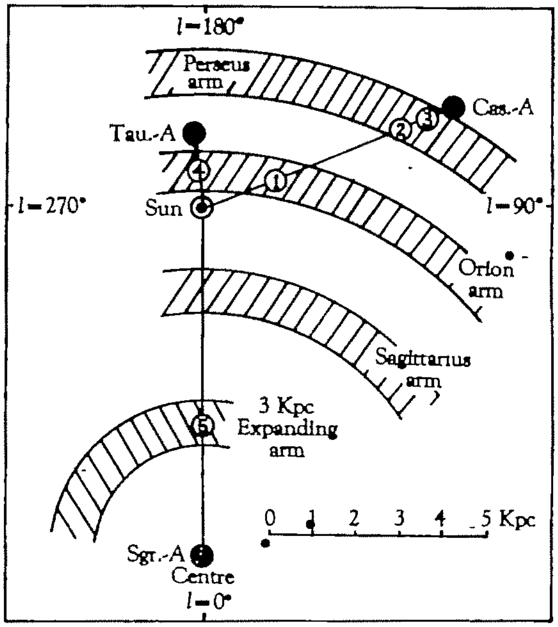

Fig. 1. Schematic diagram of the neutral hydrogen arms of the Galaxy showing the positions of the radio sources Cassiopeia-*A*, Taurus-*A* and Sagittarius-*A* (filled circles), and the absorbing clouds (open circles) studied in this investigation

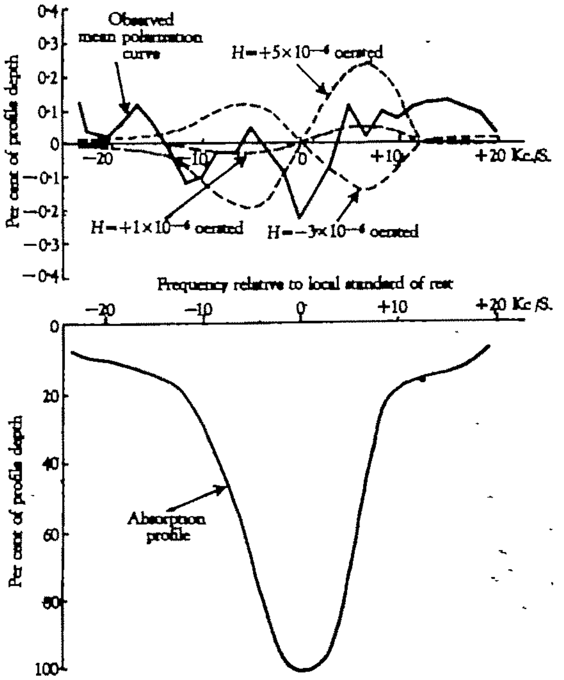

Fig. 2. Limits of the magnetic field in the Orion arm cloud in the direction of Cassiopeia-*A*. The full-line plot is the mean of the observed scans and the dotted curves are those for the best fitting magnetic field and the fields a standard deviation different. The plot underneath shows the shape of the Orion arm absorption profile

estimated standard deviation. The magnetic field is tabulated as positive when directed away from the observer.

These results give no positive evidence for a magnetic field in any of the clouds studied. The line-of-sight component of the magnetic field in each of the three clouds in the direction of Cassiopeia-*A* is less than 1 × 10⁻⁵ oersted, and indeed for the case of the Orion arm cloud it is less than 0·5 × 10⁻⁵ oersted.

Table 1. Limits of the Magnetic Field determined from Absorption Features in Three Intense Radio Sources

	Source	Velocity displacement of absorption feature (km./sec.)	Galactic longitude (new co-ordinates)	Magnetic field (units of 10⁻⁶ oersted)
1.	Cassiopeia-*A* (23*N*5*A*)	− 1 (Orion arm)	112°	+ 1 ± 4
2.	Cassiopeia-*A* (23*N*5*A*)	− 38 (Perseus arm)	112°	+ 1 ± 7
3.	Cassiopeia-*A* (23*N*5*A*)	− 48 (Perseus arm)	112°	− 3 ± 7
4.	Taurus-*A* (5*N*2*A*)	+ 10 (Orion arm ?)	185°	+ 10 ± 10
5.	Sagittarius-*A* (17*S*2*A*)	− 53 (Expanding arm)	0°	+ 14 ± 40

If the magnetic field configuration follows the spiral pattern of the Galaxy the line-of-sight to Cassiopeia-*A* would make an angle of about 30° to the direction of the field. Accordingly the magnitude of the actual field has limits only 15 per cent greater than those given for the Cassiopeia-*A* features shown in Table 1.

The measurements on the Taurus-*A* cloud gave a higher limit to the magnetic field because it is a weaker absorption feature. Nevertheless they show that the radial field of the Galaxy near the Sun is less than 2 × 10⁻⁵ oersted. The cloud studied in the Sagittarius-*A* spectrum shows a radial component of magnetic field less than 5 × 10⁻⁵ oersted. It lies in the 3 kiloparsecs expanding arm where anomalous conditions occur[2] and the magnetic field may be substantially higher than farther out in the galactic disk near the Sun. Here the neutral hydrogen gas is expanding outwards at 50 km./sec. having left regions nearer the centre where the expansion velocity is 200 km./sec.

The upper limit of the magnetic field in the disk of the Galaxy set by this experiment is smaller by a significant factor than that demanded by some theories. The theory of Biermann[3], which explains the synchrotron radio emission from the Galaxy in terms of electrons derived from cosmic rays, requires fields of 2–3 × 10⁻⁵ oersted in the galactic disk. The model of the Galaxy proposed by Elvius and Herlofson[4] postulates a magnetic field of 2 × 10⁻⁵ oersted. Attempts to understand the polarization of starlight[5] have often required fields of greater than 1 × 10⁻⁵ oersted. Such theories may have to be reconsidered in view of the present results.

We wish to thank Prof. A. C. B. Lovell, director of the Laboratories, for making available the facilities for this research. The help gained from discussion with Prof. R. Hanbury Brown is also gratefully acknowledged. The programme of research was supported by a grant from the Department of Scientific and Industrial Research.

COMPARISON OF THE CHEMICAL COMPOSITION AND MAGNETIC PROPERTIES OF TEKTITES AND GLASSES FORMED BY FUSION OF TERRESTRIAL ROCKS

By Dr. IRVING FRIEDMAN, Dr. ARTHUR THORPE and Dr. FRANK E. SENFTLE
U.S. Geological Survey, Washington, D.C.

It has been suggested by some investigators[1] that tektites are of terrestrial origin and hence were formed in an atmosphere of composition similar to that surrounding the Earth to-day. In particular, Hawkins[2] has pursued the hypothesis that tektites may be a special form of fulgurite. In order to shed more light on this problem an attempt has been made to determine the changes in chemical composition that silicate rocks would undergo when heated to 2,000–3,000° C., in air in a solar furnace. The fused materials were analysed chemically and magnetically before and after fusion.

* Analyses performed by Rapid Rock Analysis Group, U.S. Geological Survey.

The rock samples were heated by placing them at the focal spot of the solar furnace at the U.S. National Bureau of Standards. This unit consists of an 8-ft. square mirror controlled photoelectrically by a heliostat and adjusted to reflect the Sun's light into a 60-in. diameter parabolic mirror of 24-in. focal length. A relatively large specimen is fastened in a holder that can be moved independently around three mutually perpendicular azimuths by means of individual electric motor drives. The operator can view the sample through a small hole in the centre of the parabolic mirror. The hot focus can thus be moved to different parts of the specimen by the motor drives on the sample holder in order to melt an area larger than the focal area. The construction of the furnace makes it necessary to have the sample mounted vertically, and any molten material produced tends to drop off after a relatively short time. This limits the time of heating for those rocks the melts of which are very fluid, such as basalt. In the case of the bentonite and basalt glass, the material dropped off after a few minutes of heating at temperatures estimated to be more than 2,500° C. The more siliceous melts, on the other hand, were far more viscous, and the molten area could be kept hot for periods of 1/2 hr. or more before they dropped off.

The temperature measurements were crude estimates, at best. The melts were far from black bodies, and tended to reflect the Sun into the optical pyrometer, which tended to make the temperature readings high. The value of 2,500 ± 300° C. is thus a rough estimate corrected for reflexion.

Total chemical analyses by the method of Shapiro and Brannock[3] were made on all the unheated and fused specimens. As magnetic measurements have been used to show the state and quantity of iron in glasses (see Senftle and Thorpe[4]), the magnetic susceptibility and saturation magnetization were also measured on all samples before and after heating. The results listed in Table 1 have been reduced to a water-free basis.

In tektites the monovalent alkali oxides (K_2O, Na_2O) are generally lower than the divalent oxides (FeO, MgO, and CaO). It was expected, therefore, that due to loss of volatiles, the chemical composition of the fused rocks might approach the average composition of some of the tektites as shown in Table 2. The loss of silica and alkalis and the concentration of alumina are apparent in most of the samples. However, the changes are small, and one can conclude that much higher temperatures and/or longer periods of heating would be necessary to change the composition of even an obsidian to that of an indochinite, two materials the silica and alumina composition of which are fairly close even before heating.

Another interesting observation is that the ferric–ferrous iron ratio in the fused samples tends to approach the average value of 0·4. The iron in the basalt and rhyolite glasses oxidized whereas that in the obsidian and other more oxidized materials was reduced. The reduction of ferric to ferrous iron in air begins at some temperature between 1,300° C. and 1,400° C. primarily due to the decomposition of Fe_2O_3. Abou-el-azm[5] has examined the change in composition of many silicate glasses with temperature, and has shown that the ferrous iron increases rapidly above 1,400° C. By extrapolation of his results it can be shown that in the region of 1,700° C. the conversion of Fe^{3+} to Fe^{2+} reaches a limiting value. He has also found that if the ferric–ferrous ratio is low (high ferrous iron) initially, part of the ferrous iron tends to be oxidized due to contact of the glass with the air at the surface of the melt, or by oxygen contributed by the other constituents. His work indicates that the melt approaches an equilibrium between Fe^{3+} and Fe^{2+} depending on the available oxygen and the temperature of the melt. Thus, it can be expected that as the temperature is raised above 1,700° C., the ferric–ferrous ratio of fused rock will approach a limiting value for a given oxidizing atmosphere.

In the experimental work reported here the fused rock glass was in contact with 1/5 atmosphere of oxygen at approximately 2,500° C. At this oxygen pressure and high temperature the ferric–ferrous iron ratio appears to approach an equilibrium value of about 0·4. In comparison, the same ratio for tektites is somewhat smaller as shown in Table 2. This difference in the ferric–ferrous ratio between fused rocks and tektites suggests that the tektites were probably heated in a gas phase the partial pressure of oxygen of which was less than 1/5 atmosphere.

If the last heating of the tektites occurred as they passed through the atmosphere, it is possible that the major portion of the heating occurred in the upper atmosphere at oxygen pressures many orders of

Table 2. Average Composition of Tektites (Computed from Data given by Barnes, ref. 6)

* See Senftle, F., and Thorpe, A. (ref. 4).

magnitude less than at the surface—perhaps as low as 10^{-4} to 10^{-6} atmosphere. As the air density increased, the objects were slowed down and the heat produced was lost more efficiently. This is in accordance with the observation that stony meteorites that are heated sufficiently in their passage through the upper atmosphere to form a fusion crust are cool enough to handle by the time they strike the Earth.

The saturation magnetization, σ, of the molten rocks is similar to that reported for tektites. The data in Table 1 show that, after melting, the magnetization dropped to zero (with the exception of the sand specimen from Big Stone Gap, Virginia) in accordance with similar measurements on tektites reported by Senftle and Thorpe[4]. Zero magnetization indicates complete solution of the iron, and one therefore concludes that complete solution of the iron has taken place in these melts within the heating time. The above authors have previously shown evidence that the minimum heating time necessary to dissolve particulate iron oxide is probably of the order of 1 min. for temperatures of the order of 2,000° C. and maybe slightly less for higher temperatures. For the experimental temperatures and chemical composition, the heating time shown here can be considered ample to produce tektite-like glass. The heating period of tektites is probably greater than one minute, but not necessarily larger than fifteen minutes, except perhaps for specimens containing a very high silica content, for example, Libyan Desert glass (this glass is not considered to be a true tektite by some investigators).

The change in the value of the magnetic susceptibility is not considered too important from the point of view of the formation of tektites. Its magnitude simply reflects the total iron content, and the observed changes can be explained by the solution of the iron in the glass. Thus, the high susceptibility for the sandstone is due to incomplete solution of the iron in the glass, whereas the high value for basalt glass is due to the high iron content. The rest of the rocks contain less iron than most tektites, and hence their corresponding magnetic susceptibilities are lower than those of tektites.

Table 3 shows the results of the magnetic measurements on the unheated and fused rock in which tektites have been found. The values of the magnetic susceptibility and saturation magnetization are not too unlike that for tektites in general, but the results show that the magnitude of the susceptibility is quite different from that of the tektites found in the area. It indicates that the moldavite contains less iron than the enclosing sand, whereas bediasites contain more iron than the local rock. One cannot help but conclude that tektites are not formed from the local rock in which they are found, for example, by local surface heating or effects of lightning.

In summary, the chemical and magnetic measurements of several types of rocks have been made before and after fusing at 2,500° C. in air at atmospheric pressure. The changes in composition indicate that tektites were either (*a*) melted at temperatures in excess of 2,500° C., or (*b*) heated at this temperature for periods in excess of 20 min. Thus, the small change noted in the composition suggests that the observed composition of tektites probably reflects the composition of the material from which they came. The larger ferric–ferrous ratio of the fused rocks compared to that of tektites suggests that the tektites were melted in an oxygen atmosphere the pressure of which was less than that on the surface of the Earth. The changes observed in the magnetic properties indicate that a heating period of 15–20 min. at 2,500° C. is sufficient to produce magnetic properties similar to those of tektites, but does not preclude the possibility of longer periods of heating. Comparison of the magnetic susceptibility of tektites and the melted rock from the same location show that tektites could not be formed from the rocks in which

Table 3. Comparison of the Magnetic Properties of Tektites and the Glass made from the Enclosing Rock Formation

Sample	Magnetic susceptibility χ (e.m.u./gm.)	Saturation magnetization (e.m.u./gm.)

ZONE ELECTROPHORESIS OF ANTHOCYANINS

By Prof. P. MARKAKIS

Food Science Laboratory, Michigan State University, East Lansing, Michigan

THE molecule of anthocyanins has been considered ionic since the classical studies of Willstätter[1]. Migration of these pigments in an electric field should, therefore, be expected. Recently, Schmidt and Schönleben[2] and Wyler and Dreiding[3] observed that the red beet pigment, the anthocyanic nature of which is still in doubt, does show electrophoretic migration.

In this article it is reported that the typical anthocyanins of sour cherries, strawberries, plums and roses, when placed within an electric field applied across filter paper (or cellulose powder), move to the anode or the cathode, depending on the pH of the electrolyte solution. The isoelectric points of the two anthocyanins of the tart cherry, *Prunus cerasus* L., var. Montmorency, are also given, along with the observation that the isoelectric points of these anthocyanins seem to coincide with the pH at which the pigments display minimum colour.

The Montmorency cherry pigments were in a 70 per cent ethanol extract saved from a parallel experiment on the pectins of this fruit. This extract was stored at 0° C. and aliquots were concentrated at 40° C. in a vacuum, rotating evaporator. The strawberry anthocyanins were extracted with n-butanol, and those of the dried rose petals or plum skins with methanol. The extracts were shaken with enough petroleum ether, or ether and petroleum ether, to precipitate the pigments in a small quantity of 1 per cent aqueous hydrochloric acid, and this concentrated aqueous solution of pigment was subjected to paper electrophoresis.

The concentrates of the anthocyanins of various origins were streaked on strips of a Spinco model *R* paper electrophoresis apparatus. A variety of electrolytes such as phosphoric acid, acetic acid, formic acid, or their sodium salts, in concentrations of 0·1 or 0·01 M, were found suitable for the electrophoretic separation of the pigments. After the application of a voltage gradient of 7–8 V.cm.$^{-1}$ for 5–10 hr., the pigments generally moved toward the cathode, if the pH of the electrolyte was below 6, and toward the anode if the pH was above 7. To render the pigmented zones more visible after runs close to the isoelectric point or the alkaline side of it, the strips were exposed to hydrochloric acid fumes. Fig. 1 is a photograph of the strips after electrophoresis of the cherry anthocyanins at various pH.

In order to obtain larger quantities of purified cherry anthocyanins for further study, the pigments were separated by means of a Reco model *E*-800-2 flat electrophoresis apparatus. A 5-mm. thick layer of Whatman standard cellulose powder, suspended in 1 M acetic acid, was applied on the plate of the apparatus and the pigment concentrate was streaked at three or four different places across the field. With a voltage gradient of 10–15 V.cm.$^{-1}$, satisfactory separation of the two cherry anthocyanins was achieved after 8 hr. The coloured zones were removed, eluted with methanol, and the eluate was concentrated in the vacuum evaporator at room temperature. The electrophoretically isolated pigments showed the same mobilities on the strip electrophoresis apparatus as those displayed when

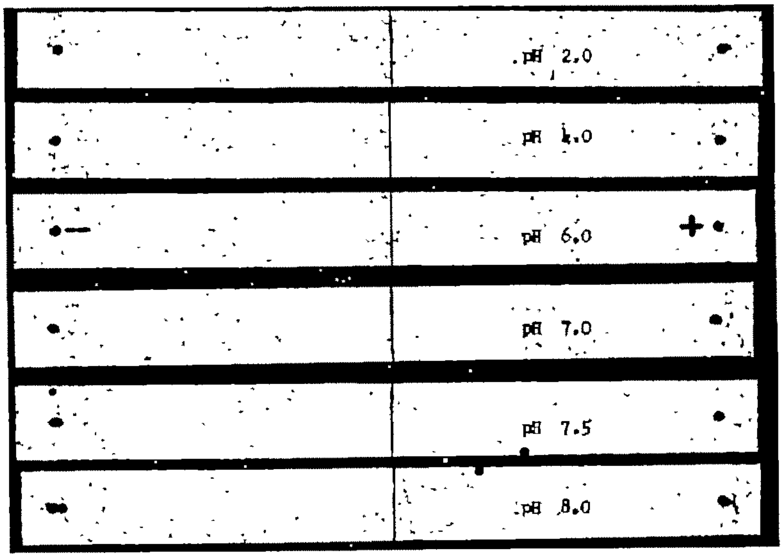

Fig. 1. The anthocyanins of *Prunus cerasus* L. var. Montmorency after paper electrophoresis in a Spinco apparatus. Electrolyte: 0·03 M ortho-phosphoric acid adjusted to various pH's with sodium hydroxide. Voltage gradient. 7 V.cm.$^{-1}$. Duration 5 hr. Room temperature

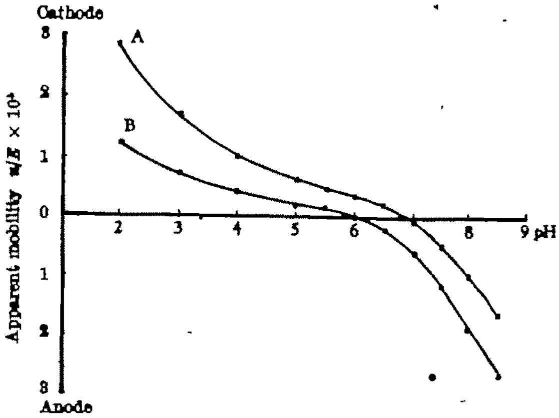

Fig. 2. Apparent electrophoretic mobilities (in cm. per sec. per voltage gradient of 1 V.cm.$^{-1}$) of the Montmorency cherry anthocyanins as functions of pH. Conditions same as in legend of Fig. 1

the original mixture was streaked. Also no difference in mobility was observed when the pigments were first isolated by means of column chromatography (performed with cellulose powder and *n*-butanol : acetic acid : water, 40 : 10 : 12·5 v/v) and then subjected to electrophoresis. The pigment which travelled the fastest in chromatography moved the slowest in acidic electrophoresis.

Consequently, the original mixture was deemed adequate for ascertaining the electrophoretic mobilities at various *p*H's and the isoelectric points of the individual cherry pigments. The mixture was further dried *in vacuo* to a syrupy mass, which was then diluted with 0·03 *M* phosphate buffer of various *p*H's and streaked on the strip apparatus. After electrophoresis under the conditions described in the legend of Fig. 1, the apparent electrophoretic mobility (not the real mobility of the molecules in the tortuous path of the paper capillaries) was calculated. The electro-osmotic correction was estimated for each *p*H by means of the dextran indicator as described by Kunkel and Tiselius[4]. The corrected values are graphically presented in Fig. 2. It appears that the isoelectric point of pigment *A* is 6·9 and that of *B*, 6·0.

To test the hypothesis that the isoelectric point and the *p*H of minimum colour display coincide, the electrophoretically isolated cherry anthocyanins were dissolved in 1 *M* citric acid–sodium hydroxide buffer of various *p*H's, and the absorption spectrum of the solutions was measured by means of a Beckman *DK*-2 recording spectrophotometer. In the red region (500–530 mμ) in which these pigments show a maximum of absorption, the least optical density was found to be very close to the isoelectric point, as is indicated in Table 1.

Since the Montmorency cherry anthocyanins have been characterized[5], it was easy to identify the electrophoretic fractions *A* and *B*. Both paper chromatography and the sodium carbonate test[6] indicated that pigment *A* is the mecocyanin and pigment *B* the antirrhinin of Li and Wagenknecht[5].

Table 1. OPTICAL DENSITIES AT 520 mμ OF THE MONTMORENCY CHERRY ANTHOCYANINS IN SODIUM CITRATE BUFFER AT VARIOUS *p*H'S

Experiments in progress on the separation of anthocyanins by paper curtain continuous electrophoresis are encouraging.

In view of the findings described, paper electrophoresis appears as a promising method of separation, purification, characterization and preparation of anthocyanins. It is still unknown, however, whether it will be as widely applicable as the chromatography of these pigments.

From the structural point of view, the formulæ proposed by Ingold[7] and Sondheimer[8] may account for the electrophoretic and chromatic behaviour of the anthocyanins studied. At the isoelectrical point of antirrhinin, for example, all eight of Ingold's forms—four tautomers differing in the distribution of the phenolic protons, each tautomer being mesomeric between a betanoid and a quinonoid form, such as the pair I and II—and Sondheimer's pseudobase III can explain the electrophoretic immobility; the pseudobase, however, may be the dominant form, since its interrupted conjugated bond system is more compatible with the lack of colour at this *p*H. On the acidic side of the isoelectric point, form IV should prevail, although the rather unstable oxonium forms involving the phenolic oxygens may be present. At *p*H higher than the isoelectric point, the oxonium configuration probably disappears and the negatively charged tautomers of type V constitute the dominant forms.

USE OF FERRITIN-CONJUGATED ANTIBODY TO LOCALIZE ANTIGEN BY ELECTRON MICROSCOPY

By RICHARD A. RIFKIND*, KONRAD C. HSU, COUNCILMAN MORGAN,
BEATRICE C. SEEGAL, ALICE W. KNOX and HARRY M. ROSE
Department of Microbiology, College of Physicians and Surgeons, Columbia University, New York

THE conjugation of ferritin with globulin, as described by Singer[1], provides a reagent which allows adaptation of the basic principle of immunofluorescent staining[2] to electron microscopy. The ferritin molecule, a protein of molecular weight about 700,000, contains a central core, 55–60 Å. in diameter, of four ferric hydroxide particles which are sufficiently dense to be readily identified in electron micrographs[3–5].

Horse spleen ferritin[6,7] (supplied by courtesy of Dr. A. Mazur, Cornell University Medical College, and the Sylvana Chemical Co., Orange, New Jersey) and antibody globulin[8] were conjugated according to Singer's method[1] with minor modifications, as follows: 4 ml. of a 1·8 per cent solution of purified amorphous ferritin were mixed with 2 ml. of 0·3 M borate buffer (pH 9·5) to achieve a final 0·1 M buffer solution. 0·12 ml. of *m*-xylylene di*iso*cyanate (supplied by courtesy of the Carwin Co., North Haven, Conn.) was added, the mixture was stirred for 45 min. at 0° C., left to stand 1 hr. and centrifuged for 30 min. in the cold. The supernatant was removed from the unreacted xylylene di*iso*cyanate, which was discarded. The ferritin–xylylene *iso*cyanate complex and the immune globulin were mixed on a weight-for-weight basis and buffered with 0·1 M borate buffer. Sodium chloride was added to 1 M concentration. The mixture was stirred at 4° C. for 48 hr., dialysed against 0·1 M ammonium carbonate overnight and dialysed an additional two days with 0·1 M phosphate buffer (pH 7·5). It was then centrifuged, the supernatant passed through a 'Millipore' filter and stored for use.

In order to ascertain the effect of conjugation on the reactivity of antibody with its homologous antigen, a hæmagglutination system with conjugated antibody to purified bovine serum albumin was used. By means of Boyden's technique[9], as modified by Heller *et al.*[10], tanned sheep erythrocytes were coated with bovine serum albumin and exposed to serial dilutions of ferritin-anti-bovine serum albumin. It was found that conjugation with ferritin did not reduce the hæmagglutinin titre of the anti-bovine serum albumin globulin. The agglutinated red cells were washed, lysed with saponin, washed again repeatedly and dried from suspension on 'Formvar'-coated grids. Electron microscopic examination revealed numerous ferritin particles on the red cell stromata. Controls included unconjugated anti-bovine serum albumin globulin mixed with ferritin, a non-specific ferritin-conjugated antibody (rabbit anti-pneumococcus type 15 globulin) and purified ferritin alone.

The technique was applied to the identification of viral antigens in tissue using influenza virus, *PR*8 strain, which was inoculated by the allantoic route into 11-day-old chicken embryos. After incubation at 35° C. for 44–48 hr., portions of infected chorio-allantoic membranes, still attached to the egg shell, were placed for 1–60 min. at room temperature in ferritin-conjugated chicken anti-*PR*8 globulin which had been absorbed overnight with acetone-extracted chicken embryo powder. (This anti-*PR*8 globulin had not lost any appreciable hæmagglutinin-inhibition titre in the course of conjugation with ferritin.) After washing in Tyrode's solution the membranes were detached from the shell, fixed for 20 min. in buffered osmium tetroxide, dehydrated in graded dilutions of ethanol, trimmed, embedded in N-butyl methacrylate, sectioned on a Porter–Blum microtome and examined in an R.C.A. *EMU-2E* electron microscope.

In work using the fluorescent antibody technique, it has been repeatedly demonstrated that in the course of influenza and fowl plague infection viral antigen eventually concentrates at the cell surface[11–13]. Previous work in this laboratory has elucidated the morphology of the virus and shown that it differentiates at the cell surface of the infected chorio-allantoic membrane[14]. Fig. 1 illustrates a thin section through the superficial portion of a chicken chorio-allantoic cell infected with *PR*8 influenza virus and afterwards exposed to ferritin-conjugated anti-*PR*8 globulin for 1 hr. (Subsequent experiments have shown that optimal specific tagging of the virus is achieved in 2 min.) The limiting membrane, which traverses the lower border, has been cut obliquely and is therefore poorly defined. Extending upward into the chorioallantoic space is a cellular protrusion. On the cellular surface are scattered oval viral particles which exhibit a poorly defined core, a dense limiting membrane and a diffuse outer coat. Serial sections[14] have shown that structural appearance of the particles depends on the level at which they are cut: they are relatively dense and sharply

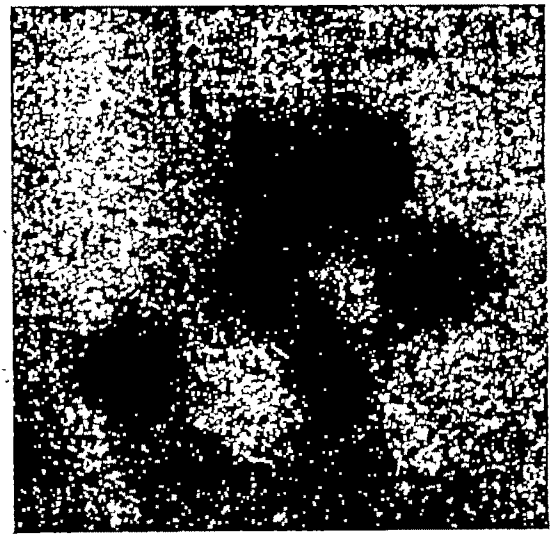

Fig. 1. Influenza virus at the cell surface. Ferritin granules associated with the viral particles are clearly visible. (×170,000)

defined when sectioned centrally, but appear less dense and more diffuse when the plane of section is eccentric. The opaque, sharply defined ferritin granules are attached to the diffuse outer coat of the virus. As may be seen in several instances, ferritin overlies the viral particle when it is eccentric to the plane of section. It is likely that with our present methods all the antibody is not conjugated with ferritin and hence determination of the precise arrangement and number of antigenic units on the viral surface must await further study. As a control to the foregoing experiments, chorioallantoic membranes were infected with the Lee strain of influenza virus and treated in an identical manner with ferritin-conjugated anti-*PR*8 globulin. Although a few scattered ferritin granules were present on these cells, there was no predilection for the viral particles. Likewise, *PR*8-infected membranes exposed to other non-specific ferritin-conjugated antibodies (rabbit anti-pneumococcus type 15 globulin and duck anti-rabbit-globulin globulin) showed only sparse and randomly distributed ferritin particles. Further to document the specificity of the reaction, *PR*8-infected membranes were exposed to unconjugated anti-*PR*8 globulin for 1 hr., then washed and placed in ferritin-conjugated anti-*PR*8 globulin for 2 min. This resulted in no localization of ferritin on the virus, whereas an infected membrane exposed for 1 hr. to normal serum before immersion in ferritin-anti-*PR*8 globulin showed characteristic tagging of the virus.

---

* Fellow of the National Foundation.

It appears that ferritin-conjugated antibody globulin maintains its serological specificity and thus renders visible in the electron microscope the sites of antigen–antibody interaction. Within the limits of these experiments it has been shown that tagging of virus with ferritin-conjugated antibody is specifically blocked by prior treatment with unconjugated antibody globulin. Work is in progress to modify the technique so that identification and localization of intracellular antigens may become possible.

These investigations were conducted under the auspices of the Commission on Influenza, Armed Forces Epidemiological Board, and were supported in part by the Office of the Surgeon General, Department of the Army, Washington, D.C., by a grant from the National Foundation, and USNIH grant *H*-3929*C*.

IMMUNOLOGICAL RELATIONSHIPS BETWEEN THE RAT GLOMERULUS AND NEPHRITOGENIC STREPTOCOCCI

By A. S. MARKOWITZ, S. HOWARD ARMSTRONG, Jun., and DANIEL S. KUSHNER

Hektoen Institute for Medical Research, Cook County Hospital, Chicago, Illinois

FOR many years efforts have been made to establish an experimental counterpart for human glomerulonephritis utilizing the streptococcus or its products without notable success. The most recent, by Kelly and Winn[1], employed an intraperitoneal diffusion chamber containing Group *A*, type 12 streptococci. These workers reported that such a procedure led to the establishment of glomerular lesions.

Utilizing such chambers, approximately 10^8 cells of an 18-hr. culture grown in Todd–Hewitt broth were introduced and the side arm sealed off by heat-fusing a polyethylene tube. Strains *NAC*, *NV* and *NVC*, Group *A*, type 12 streptococci were obtained through the generosity of Dr. Elizabeth Potter, Dept. of Medicine, Northwestern Medical School. All strains were originally isolated from the throats of acute glomerulonephritic patients. The chambers were inserted into the peritoneal cavity of female, Holtzman strain rats weighing 150 gm.; removed after 72 hr. and the animals killed one, two, and four weeks from the date of insertion of the chamber. In all instances the kidneys appeared both grossly and histologically normal, that is, within the limits of histological variation in normal rats which show focally increased cellularity of glomeruli and rare casts within tubules. Especially within this context, histopathological interpretations have been made initially by several observers without prior knowledge of the experimental procedure employed and afterwards reviewed in the light of such knowledge. (We are indebted to Dr. Paul B. Szanto, director of pathology of Cook County Hospital, for his critically cautious counsel in histological interpretation as well as for the support of his department's facilities.)

Studies of the virulence of the strains employed revealed no useful LD_{50}, since 10^8 cells failed to affect a single mouse. Virulence enhancement by means of mouse passage was then instituted with one of the strains, *NAC*. The first passage required intraperitoneal introduction of the organisms with an equal volume of a 5 per cent suspension of hog gastric mucin in order to obtain sufficient numbers of bacteria for subsequent splenic homogenate transfers. After 27 passages the *NAC* strain presented an LD_{50} of 10^2 and was then sub-labelled NAC_v.

Introduction of the NAC_v strain into the chambers, implantation for 72 hr. and killing of a group of 12 rats at four weeks consistently produced lesions the maximum degree of which is illustrated in Fig. 1. (A representative glomerulus from a control animal is illustrated in Fig. 2.) The glomerular lesions never approached, either in intensity or in diffuseness, those we have seen in initial biopsies of streptococcal related acute glomerulonephritis in the human. The spotty glomerular changes were uniformly accompanied by eosinophilic casts both in proximal and distal convoluted tubules in numbers far in excess of those seen in control animals.

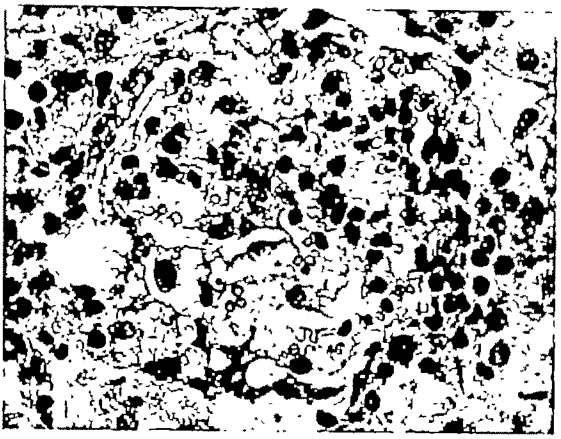

Fig. 1. Cellular, swollen glomerulus Filling out of Bowman's space with free red cells in space; sparse polymorphonuclear leukocytes in glomerular tuft. (×c. 360)

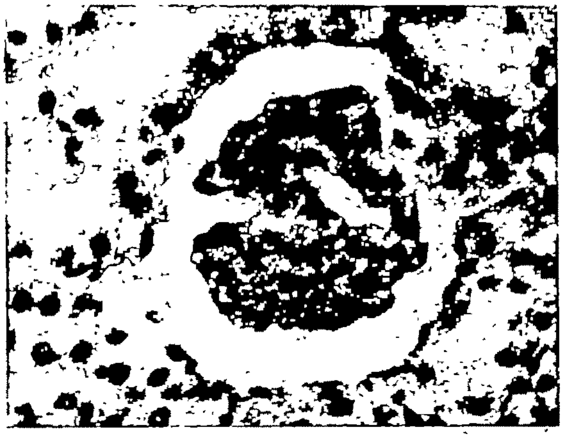

Fig. 2 Normal glomerulus. (×c. 360)

Subsequent to these experiments an additional strain, A_{12}-41, was obtained which after five passages in mice had an LD_{50} of $2\cdot5 \times 10^1$ and within peritoneal chambers induced similar histological changes in a group of 12 animals. (We are indebted to Dr. J. Hayashi, Department of Biochemistry, University of Illinois Medical School, who obtained this Red Lake strain for us through the courtesy of Dr. W. Schmitt of the Cuyahoga County Hospital, Cleveland, Ohio.)

The virulent state of these two strains was maintained by quick freezing (acetone-'dry ice') a 1-ml. broth suspension in ampoules and storing in the cold at −15° C. For diffusion chamber experiments the content of the ampoule was permitted to thaw at room temperature and transferred to a tube of Todd–Hewitt broth. The resultant 18-hr. culture was then introduced into the chambers.

Based upon the results presented above, no satisfactory conclusion could be reached as to the genesis of the renal lesions, that is, toxic or immunological. It has been suggested by one of us (A. S. M.) that the nephritogenic streptococcus and the glomerulus may share an antigenic component in common. Accordingly, an extraction procedure was elaborated in an effort to isolate a soluble, antigenic component from the streptococcus capable of inducing the formation of nephrotoxic antibody.

Whole, heat-killed, washed, 18 hr. old A_{12}-41 cells geny of quick-frozen cells) were suspended in phosphate buffer, *p*H 8, and trypsinized for 4 hr. at 37° C. The supernatant, after removal of particulate matter by centrifugation and Seitz filtration, was treated with an equal volume of 'Genetron' (trifluorotrichloroethane) in the manner of Markowitz and Henderson[2]. The aqueous phase of this treatment was dialysed against water in the cold for 24 hr. and then lyophilized. Rabbits were immunized with 75 mgm. of the extract combined with Freund's adjuvant and the serum obtained was assayed for nephrotoxic activity in the rat. Serum dosages of 0·01 ml. per gm. of body-weight were introduced into the tail veins of a group of 12 rats. Equivalent amounts of control rabbit serum (obtained from animals immunized with Freund's adjuvant plus 0·89 per cent sodium chloride solution) were likewise introduced into a similar group of animals. Fig. 3 represents the most pronounced of glomerular lesions observed in the experimental group killed two weeks after introduction of serum. The sparse focal distribution of such glomeruli, in contrast to the clearly abnormal numbers of tubular casts (also illustrated in Fig. 3), cannot be overemphasized. The group receiving control rabbit serum presented normal renal histology within the range indicated earlier.

Using isolated whole rat glomeruli prepared according to Greenspon[3] as the starting material and the same extraction procedure indicated above, a material was

A new technique for separation of substances of different molecular sizes

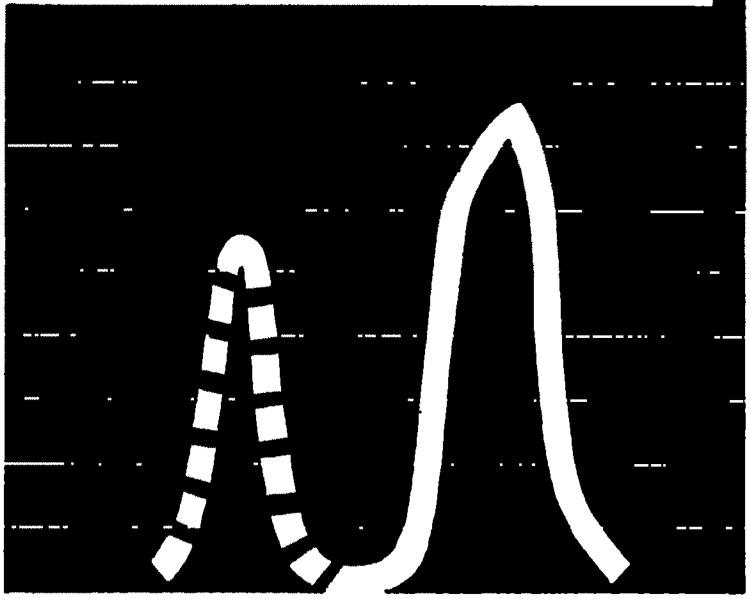
Sephadex

IN GEL FILTRATION

SEPHADEX is now available in three types, for a multiplicity of applications, such as:

Desalting of protein solutions
Fractionation of polymers
Group separation of biological extracts

GEL FILTRATION with SEPHADEX is simpler and far more rapid than previous procedures



Lower limit for complete exclusion:

Sephadex G - 25 Mw 3,500 - 4,500
Sephadex G - 50 Mw 8,000 - 10,000
Sephadex G - 75 Mw 40,000 - 50,000

obtained which also stimulated production of a nephrotoxic antiserum. The assay, which was conducted in a group of 12 rats, again revealed that the maximal glomerular changes (illustrated in Fig. 4) were of modest degree and focal in distribution; many glomeruli in the experimental animals could not with reliability be distinguished from glomeruli in certain control animals, while a clear distinction between experimental and control groups could be made by reason of numbers of casts and other tubular differences in the former. All three groups of experimental animals displayed proteinuria greatly in excess of control animals.

Based upon electrophoretic analysis of the extracts which indicated heterogeneity and the focal and modest character of the glomerular lesions in the experimental animals, the necessity for more potent antisera directed against further purified, monospecific entities is recognized.

It would appear from the observations presented in this preliminary communication that the diffusion-chamber-streptococcus induction of experimental glomerulonephritis has probably an immunological basis and that common antigen(s) may be shared between the nephritogenic streptococcus and the rat glomerulus. Additionally, there is a clear-cut relationship between the virulence and the nephritogenic capacity of our strains.

This work was supported by the Elizabeth McCormick Research Foundation. The senior author wishes to express his appreciation to the Board of Commissioners of Cook County and to Warden Fred A. Hertwig, Cook County Hospital, for their interest and development of facilities for basic medical research.

BEHAVIOUR OF PAPER DURING TENSILE STRAINING

By A. E. RANGER and L. F. HOPKINS

Bowater Research and Development Co., Ltd., Research Division,
Northfleet, Kent

FOR many years the view has been widely held that the final fracture in the tensile testing of paper is governed by failure of inter-fibre bonds, and that very few of the fibres themselves are actually broken. Recent work by Van den Akker[1], however, in which individual fibres in the failure region could be observed, has cast doubt on this belief. Of those fibres involved in the fracture a high proportion was found to be ruptured—as many as 77 per cent in one instance. Although Van den Akker is careful to point out that many of the fibres failed after the paper had started to fracture and that such fracture could still be initiated by bond failure, he nevertheless concludes that: "the strength of the fibres of a papermaking pulp is of much greater importance than had hitherto been generally recognized".

A critical analysis of the evidence in favour of inter-fibre bond failure as opposed to fibre failure had led us, independently, to the same conclusion and to attempt to describe the tensile behaviour of paper on a basis of predominance of fibre failure.

A difficulty arose at the outset when considering the increase in optical opacity which occurs during the plastic stage of straining. Although generally accepted as indicating fracture of inter-fibre bonds, this change could also be due to the rupture of fibres. Experiments designed to detect such pre-fracture damage were carried out, but with negative results.

A way was therefore sought of reconciling the two apparently contradictory ideas—that of inter-fibre bonds being broken during the straining process, and that of the final fracture being predominantly governed by fibre failure.

During the course of previous experiments it had been established that a paper strip undergoing longitudinal extension contracts significantly in width. One effect of this is that fibres oriented approximately at right angles to the direction of tension are subjected to longitudinal compressive forces. It is suggested that, because of their slenderness, these fibres will tend to buckle at comparatively low strains, and in so doing will tend to peel apart from those fibres which are, because of their orientation, held in tension. Such a process can occur at a much lower stress-level than rupture by simple shear, which is the predominant mode of failure of those bonds which are ruptured at final fracture of the paper. The complete picture, then, is of the tensile strength of the fibres being intermediate between two effective bond 'strengths' which differ by virtue of the two distinct modes of rupture.

This proposed mechanism of bond failure during plastic straining has been invoked to explain the phenomenon of strain lines. When a strip of tracing paper is strained, the increase in opacity can be followed visually, and it is seen that the opaque regions form a reticulate pattern orientated at a characteristic angle to the direction of tension. Rance[2], who first directed attention to these strain lines, also demonstrated their existence in other types of paper by a method analogous to the brittle lacquer technique in stress analysis, which incidentally showed that they are regions of high local deformation.

The failure of a small group of bonds by peeling will raise the stress-level in the immediate vicinity and give rise to a band of local deformation; but if the relative movement of the two parts of the paper is parallel to the direction of tension the deformation will be limited, since there will be no tendency for further fibre buckling to occur. In addition, a simple analysis shows that the deformation band in this case would be perpendicular to the direction of tension, which contradicts experience.

However, if the two parts of the strip tend to separate by a shear or slip movement along the band of deformation itself, these difficulties do not arise. Such movement would automatically subject more fibres to compressive forces and lead to further bond failure by peeling.

An analysis of the situation was made, based on this assumption of shear movement, which led to a prediction of the angle at which such a band of local deformation should occur. An 'orientation factor' was included in the analysis to facilitate comparison with machine-made paper, which is anisotropic with respect to fibre orientation. Fig. 2 shows the predicted variation of strain-line angle with strip direction, the angles being defined in Fig. 1.

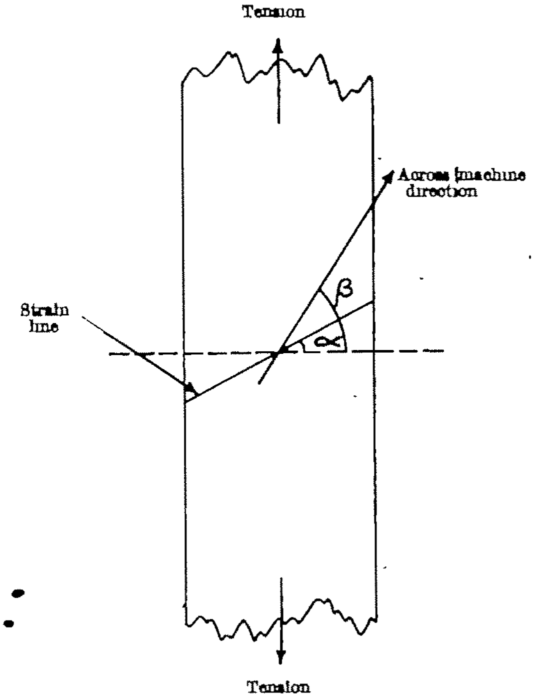

Fig. 1. Orientation of strain line and machine direction with respect to test strip

In view of the assumptions made in the mathematical treatment and the uncertainty involved in the degree of fibre orientation in machine-made paper, the agreement in the case of tracing paper is perhaps not unsatisfactory, especially since in this instance it is not possible to verify the complete variation of strain-line angle because the pattern becomes indistinct as the machine direction is approached and the angles can no longer be measured. However, the proposed mechanism of formation of strain lines, despite its genesis, does not apply only to strong papers, and it was found that very weak papers (for example, from an unbeaten pulp) tended to fracture along a diagonal line which was tentatively identified as a strain line. A technique evolved from this observation whereby strips of strong machine-made paper were wetted locally and thus weakened excessively and the angle of the fracture was measured. By this means the complete variation of 'strain-line' angle could be investigated, and this result also is shown in Fig. 2.

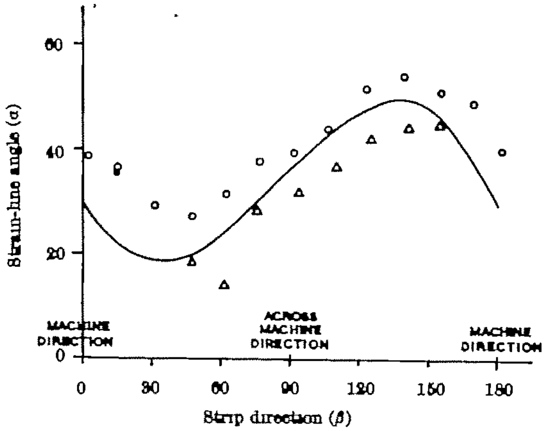

Fig. 2. Variation of strain-line angle with strip orientation. Δ, tracing paper; O, wetted Kraft paper (fracture angle); —, theoretical curve

Wetted strips also show quite clearly the shear movement at fracture and the local increase in paper thickness caused by the buckling of fibres (Fig. 3).

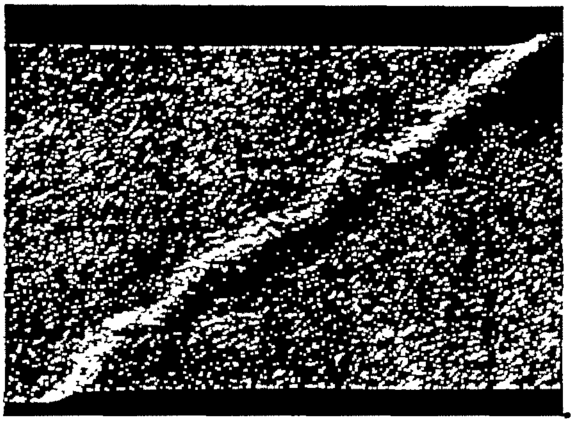

Fig. 3 Shear movement and local increase in thickness with wetted paper

This theory of paper behaviour during tensile straining leads to several interesting predictions which are being investigated, and it is hoped to present a full account of this work in September 1961 at the Fundamental Research Symposium which is being organized by the Technical Section of the British Paper and Board Makers' Association.

PHYSICS

Pulse-shortening in Electron Linear Accelerators

During the past few years several electron linear accelerators have been designed in Great Britain, France and the United States to support pulse currents in excess of 250 m.amp. for durations of 1–10 μsec. Many of these machines have failed to reach design performance due to a phenomenon which has come to be known as 'pulse-shortening'. This effect appears as a premature termination of the output electron pulse and occurs at pulse currents in the range 300–600 m.amp. and pulse-lengths of 1 or 2 μsec. depending on the particular machine. Further increase of pulse current is possible only at the expense of pulse-length. The current pulse and the radio-frequency loading are normal until the point in time at which 'shortening' occurs. Beyond this point, where there is typically a 0·1/0·2 μsec. jitter of the trailing edge of the current pulse, there is little or no electron current and usually the radio-frequency pulse shows an increase somewhat above the normal loaded level but does not reach that corresponding to zero beam.

The values of current quoted above refer to the onset of pulse-shortening at the S-band (3,000 Mc./s.). At least one machine constructed in the United States operates on the L-band (1,250 Mc./s.) and is reported as exhibiting pulse shortening but at much higher pulse currents (1–2 amp.). Conversely X-band (9,250 Mc./s.) accelerators designed in this laboratory have shown this effect at about 40 m.amp. It would appear that for accelerators operating at different frequencies but of similar energy gain and length the current obtained at the onset of pulse-shortening is proportional to $1/f^3$.

Our experiments on a single accelerator section have shown that pulse-shortening occurs first at the high-energy (low radio-frequency power) end of the accelerator wave-guide, and that the buncher and first half of the accelerator are capable of supporting rather more than the design current and at least three times the current required to produce shortening in the last half. It has been shown also that the current at which pulse shortening occurs is proportional to the radio-frequency power-level in the accelerator tube. If the mechanism of pulse-shortening is a 'field effect', we might expect to increase significantly the current obtainable by designing the guide to use feedback or more conveniently by the use of a constant-field design.

A 'constant-field' accelerator has been constructed to operate at the X-band and has yielded currents in excess of 100 m.amp. without showing pulse-shortening as compared to 40 m.amp. for the equivalent constant-impedance design. This increased current is normal and is limited by the radio-frequency power available.

If both 'constant-field' and 'feedback' accelerators yield this increased current it would seem that the pulse-shortening mechanism is a 'field' effect associated with low values of field in the normal mode. If, however, the 'constant-field' solution is the only successful one, then it appears that higher order spurious radio-frequency modes may be responsible, as has been suggested by other workers in this field. Investigations of the free space wave-length and type of such modes with a phase velocity equal to that of light have been made by K. W. Robinson, Cambridge Electron Accelerator Project (private communication), and W. Gallagher, Stanford University, California (private communication).

Further work on this problem is being carried out and will be reported shortly.

We wish to thank Dr. C. F. Bareford, managing director of Vickers Research, Ltd., for permission to publish these preliminary results of our investigations.

Dependence on Latitude of the Amplitude of the Diurnal Variation of Cosmic Rays

The solar diurnal variation of cosmic-ray intensity is usually assumed to be due to the rotation of the Earth in a cloud of particles. The velocity of the latter should be randomly distributed with a small additional component in one direction, thus constituting a kind of particle wind. For various reasons it can be assumed that this wind is following the Earth, approximately parallel to its orbital plane[1]. The yearly mean amplitude of the diurnal variation should then have a maximum for primary particles having asymptotic directions approximately parallel to the equatorial plane. It should have a minimum for primaries with asymptotic directions parallel to the Earth's axis of rotation. For an experimental study of the relative magnitude of the amplitudes in these directions, it is necessary to record the variations of cosmic-ray intensity with inclined counter telescopes. However, it is difficult to gain access to both directions at one and the same point on the Earth's surface.

From the terrella experiments by Brunberg[2], it was found that one of the desired directions could be recorded with an inclined counter telescope at Uppsala, while the other direction could be recorded in the same way from a station in the Arctic. What seemed most promising, however, was the fact that not only could the two stations be linked together by a second directional telescope in each place, but also the station at Kiruna could serve as an extra link[3]. In August 1957 an Arctic station was erected at Murchison Bay, Spitsbergen.

Telescopes with a zenith angle of 30° could be used in all the three places. The telescopes at Uppsala (lat. 59·9° N., long. 17·9° E.) and Murchison Bay (lat. 80·1° N., long. 18·3° E.) should point in the east

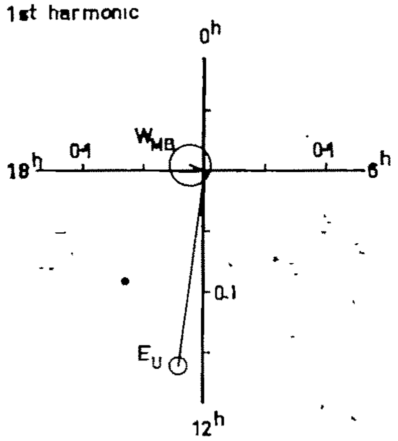

Fig. 1. Harmonic dial for the diurnal variation recorded by the east-pointing counter telescope at Uppsala (E_U) and by the west-pointing telescope at Murchison Bay (W_{MB})

and west directions, those in Kiruna (lat. 67·8° N., long. 20·4° E.) north and south. The axis of the east-pointing telescope at Uppsala corresponds to primaries entering the geomagnetic field in an asymptotic direction making an angle of 14° with the equatorial plane of the Earth. The axis of a west-pointing telescope at Murchison Bay corresponds to primaries making an angle of 82° with the equatorial plane. The values are approximate. They were derived from the assumption that the effective rigidity of the primaries[4] is 25 GeV./c. If instead the effective rigidity is assumed to be 35 GeV./c. the values will be 20° and 80°. Actually, the relation between the asymptotic directions, the axis of the counter telescope, and the rigidity spectrum cannot be calculated in a simple way[5]. However, in the present experiment, the angles of the two asymptotic directions differ in any event by such a considerable amount as to make the experiment decisive.

To secure the most reliable results, the harmonic analysis has been carried out for the mean daily variation during exactly the same days for the directions to be compared. Nevertheless, 312 days were available for the calendar year 1958. The harmonic dial in Fig. 1 suffices to show that the west-pointing telescope at Murchison Bay (W_{MB}) does not have an amplitude exceeding the standard error, whereas the east-pointing telescope at Uppsala (E_U) has an amplitude which is large compared to the standard error.

As regards the north- and south-pointing telescopes in Kiruna and the east-pointing telescope in Murchison Bay, the mean asymptotic directions make angles of 40–55° with the equatorial plane. The amplitudes of these intermediate directions are all slightly smaller than that of the asymptotic direction approximately parallel to the equatorial plane of the Earth (E_U). The primaries observed by means of the west-pointing telescope in Uppsala have asymptotic directions covering angles between 50° and 90°. The yearly mean amplitude is one-third of that of the direction parallel to the equatorial plane.

The results reported here clearly show that the amplitude of the diurnal variation decreases with increasing angle between the asymptotic direction of the primaries and the equatorial plane of the Earth. The fact that observations in two directions at the same point have given contradictory results[6] or failed to show any dependence on latitude[7] is certainly due to the difficulty in such cases in resolving the radiation cones of the primaries[8].

A full account of the present experiment will be published as soon as possible.

Fractionation of Nuclear Weapon Debris

EDVARSON *et al.*[1] report evidence for a fractionation effect noted in the radioactive analysis of samples of nuclear weapons debris collected in filters carried by a jet plane flying over central Sweden. Certain individual particles selected from the filters appeared to be rich in (zinc-90 + niobium-90) radiations and impoverished in ruthenium-103 radiations.

The purpose of this communication is to present a somewhat similar finding from an earlier study. At the time of one of the nuclear detonations at the Pacific Proving Grounds, gummed paper fall-out collectors were placed on platforms at various locations in the vicinity of the Eniwetok atoll. A few of these gummed papers were available for nuclear radiation analysis. There was a wide range of individual particle-sizes, but among the particles were some that were large enough (between about 0·3 mm. and 1 mm. diameter) to be picked off the gummed paper with tweezers. Eleven such particles were removed from two gummed paper collectors, five from a paper that had been twelve miles down-wind from the point of detonation and six from another paper that had been thirteen miles cross-wind.

Gamma-radiations from the individual particles fall into two groupings, one rich in (zinc-90 + niobium-90)

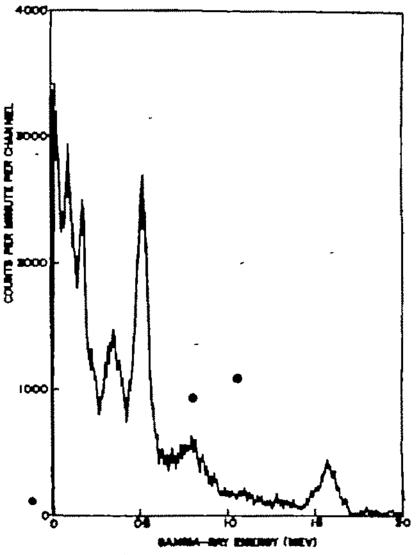

Fig. 1

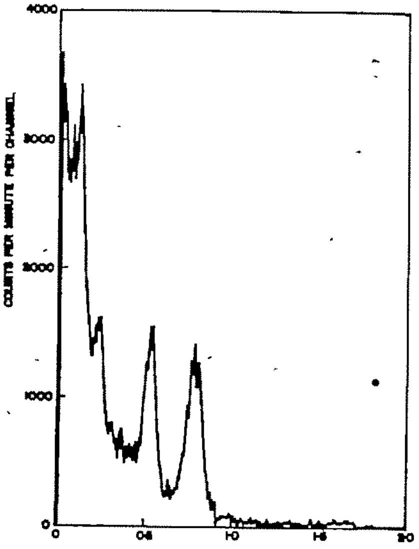

Fig. 2

radiations and the other essentially depleted of these radiations. Both types of samples were found at both stations. Pulse-height analyses, using a 4-in. diameter by 4-in. high sodium iodide (thallium) crystal, are shown in Figs. 1 and 2. Both sets of results were recorded 30 days after the detonation. It will be noted that in the spectrum of the particle from which the (zinc-90 + niobium-90) radiations at 750 keV. have been depleted, the 1·6 MeV. gamma-ray of lanthanum-140 can be observed; but this gamma-ray is not clearly distinguishable in the spectrum of the particle enriched with zinc-90 + niobium-90. A gamma-ray at about 500 keV., presumably ruthenium-103, appears in both spectra, but in much larger relative amounts in the sample depleted of zinc-90 + niobium-90.

The assistance of Mr. E. Schuert in supplying the gummed paper fall-out collectors is gratefully acknowledged.

Stepwise Ablation and Heat Transfer in Cold-Cathode Arcs

A 'cold-cathode' arc is an electric discharge in a gas or *in vacuo* with a cathode fall of about 10 V.[1] and a current density at the cathode of 10^4–10^6 amp./sq. cm.[1,2]; the intense light observed comes from the cathode vapour but not from the ambient gas, if present. The cathode temperature is much too low to give the high current density of electrons if emitted thermionically[2] from the spot, but was thought to be high enough to produce copious evaporation; pyrometric and spectroscopic temperature measurements showed 2,000–2,500° K. for many metals[3–5].

If the loss of energy by thermal conduction from the spot into a copper cathode is calculated, it is found to be equivalent to 30–100 volts for currents <10 amp.—a range free of spot-splitting; thus such arcs could only be maintained by more than 30 V. Yet measured minimum arc voltages[6] suggest a loss of heat conduction from the active spot equivalent to a few volts. Against this view can be held that such low current arcs often last for a few seconds only[7]. Moreover, with 'selected' data the calculated conduction loss from a stationary spot with $i > 20$ amp. may be only $\simeq 4$ V.; but a moving spot would certainly consume many times that value[8].

To resolve this discrepancy a thin layer of low thermal conductivity (oxides) at the spot has been postulated[9]. With oxide-free electrodes, however, the arc voltage differs little, and so one is led to doubt that the measured temperature is that of the cathode spot. In fact the real spot temperature may be much lower[8] than 2,000° K. or so, as found with mercury; there is the dense cloud of luminous metal vapour covering it[1]. If this were so, the existence of this narrow region of dense vapour above the spot—a requirement of the new arc theory[8]—cannot be explained in terms of classical evaporation; hence a new concept of evaporation must be invoked.

A similar argument applies to carbon cathodes in molecular gases[10], such arcs being stable for currents down to about 1 amp. at atmospheric pressure. As the gas pressure is gradually reduced, cathode temperature and cathode fall decrease steadily until at pressures <100 mm. mercury the thermionic spot suddenly changes into a vapour spot, with its characteristic mobility, high current density, emission of spectral lines of carbon, intense ablation and deposition of carbon on the walls of the vessel (our unpublished measurements). Again from this and other observations[10,11], one is forced to conclude that the conventional evaporation picture is untenable.

A pointer to a new solution seems to be the large energy flux from the gas into the spot maintained by unexcited and excited neutral particles, and by ions and quanta. Some of these species may ablate the cathode by a step-wise process: a lattice atom absorbs (and can re-emit) several small amounts of potential energy from incident species, and moves from its original site through intermediate positions into a final position which corresponds to an energy close to that of the boundary. From this it ultimately escapes into the gas phase[12]. A special case would be the presence of a single intermediate energy-state, analogous to a strongly adsorbed layer[13]. The concept of stepwise ablation thus involves the transfer of potential energy, and is therefore very different from that of sputtering by fast ions, for example, through momentum transfer, or classical evaporation through lattice vibrations.

The use of the new model has several consequences. First, a number of species, each of energy less than the evaporation energy λ, can between them release an atom from the lattice. Secondly, by introducing these intermediate energy-states, the flow of heat into the metal matrix can be greatly decreased.

Thus, if n species each of energy ϵ_i fall on the spot per cm.^{2} and sec., classical theory of coupled oscillators shows that evaporation (into 2π) occurs at a rate:

$$(2\lambda/kT)\,(\nu/A)\,\exp(-\lambda/kT)$$

T being the absolute temperature of the lattice determined by heat input, conduction and evaporation, ν the frequency of lattice vibrations, and A the area[12]. Hence only a small fraction of $n\epsilon_i$ contributes to evaporation, and the larger part to conduction, etc. However, with a two-stage ablation process (e_1, e_2 being the energy difference: intermediate state—vacuum and matrix—intermediate state respectively, and $\varkappa_1$, $\varkappa_2$ the corresponding transition probabilities) the energy balance in the steady state with $(e_1+e_2) > e_0 > e_1, e_2$ is:

$$n e_0 = n\varkappa_1 e_1 + n(1-\varkappa_1)\varkappa_2 e_2 + H$$

where H is the conduction loss, and $(e_1 + e_2) = \lambda$. Terms relating to electron emission, etc.[8], have been omitted for clarity.

Since $\varkappa_1$, $\varkappa_2$ have a value between 0 and 1, H is clearly smaller than in the absence of an intermediate state, when $\varkappa_1$ or $\varkappa_2 = 0$. A similar argument applies when $e_0 > \lambda$, as direct evaporation is thought to be unlikely[12]; when $e_0 < e_1, e_2$, classical theory holds.

We conclude that step-wise ablation may explain a high rate of vapour production with low loss of heat by conduction when fairly slow-moving excited particles or low-energy quanta supply energy to a cathode. Moreover, this approach may be of interest to current work on accommodation coefficients and bear on the origin of fast-particle streams emanating from arc electrodes[14,15].

We wish to thank the Director of the Electrical Research Association for the support given to our work and for permission to publish this communication.

ASTRONOMY

Origin of the Solar System

IN a recent communication[1], Dr. M. M. Woolfson has outlined a model to account for the origin of the solar system. In common with many earlier hypotheses[2], he postulates an interaction between the primitive Sun and a second star. By gravitational interactions he proposes that the Sun lost a large amount of surface matter by the breaking away of tidal bulges. This matter is envisaged to have been lost in a series of isolated events and the resulting separate sections gave rise to a planet.

While there can be no doubt that this model accounts for many of the observed regularities of the solar system, there seem to be other features that are not explained. The latter appear incompatible with any catastrophic account of planetary origins.

First, there are the known properties of meteorites[3], which indicate that the early history of the solar system was most complex and that the present planets are second—or possibly third—generation structures that were preceded by objects of approximately planetary dimensions that have broken up.

Secondly, the densities of the planets (Table 1) indicate considerable fractionation of the chemical materials from which the former arose. On catastrophic hypotheses, it is difficult to see how such fractionation could have occurred as each planet is postulated to have arisen from the same material—the solar surface.

Table 1

Planet	Semi-major axis (km.)	Mean density (c.g.s. units)
Mercury	0·387	5·05
Venus	0·723	4·87
Earth	1·000	5·52
Mars	1·523	4·24
Jupiter	5·202	1·33
Saturn	9·538	0·71
Uranus	19·190	1·26
Neptune	30·070	1·61
Pluto	39·518	2 (?)

Thirdly, the comets are part of the solar system and are not derived from interstellar material. Consequently a satisfactory account of the origins of planets must also be able to account for the origins of comets—unless it be assumed that comets are secondary features of the solar system that arose late in its history. Hypotheses postulating an evolution of the solar system from a solar nebula appear to be able to account for the origins of comets with the minimum of *ad hoc* axioms.

Other arguments that can be levelled at catastrophic hypotheses such as that outlined by Woolfson concern the improbability of forcibly ejected solar material condensing into solid planets, and the probable frequency of occurrence of solar systems in the Galaxy.

Material drawn from the Sun must be for long periods well within the Roche limit, and rapid dissipation by the action of gravitational forces would be predicted. Moreover, as Spitzer[4] has pointed out, the material would be initially at very high temperatures and pressures, and would expand under its own internal pressure and become dissipated. Consequently the prime requirement of any new catastrophic hypothesis must be a satisfactory explanation of how the ejected solar material could form into planets.

If the solar system had a catastrophic origin by a close interaction of two stars, then planetary systems must be very rare in the universe. In fact, the chances are that only the Sun and the star with which it interacted possess planets. Yet there is a growing body of evidence for the existence of extra-solar planetary systems, and there can be no doubt that many nearby stars are accompanied by dark bodies of approximately planetary size[5]. Thus, unless it be suggested that the solar system arose by one improbable mechanism while other planetary systems arose by other means, the catastrophic hypothesis is rendered very unlikely.

It would seem that the most that an interstellar interaction could have achieved is the production of a solar nebula from which the planets could have evolved; but the bulk of available evidence is against this view, as other more likely mechanisms have been suggested to account for the origin of a nebula from which planets could have been formed[6].

METEOROLOGY

Change of the Chlorine : Sodium Ratio in the Atmosphere with Altitude and Distance from the Source of Sodium Chloride, and the Distribution of Atmospheric Nitrate over the United States

The change of the chlorine : sodium ratio in rain-water with inland distance from seas is a well-known phenomenon. The experimental evidence available has lately been discussed by Eriksson[1], while further data on an almost continental scale have been supplied by Junge and Werby[2]. The latter measurements were recently used by Papée and Smith for an evaluation of trends between components of rain-water and physical variables[3]. From those computations, an indication of a decrease in the ratio between chlorine and sodium with the altitude of the sampling stations became available, and it was pointed out recently to one of us that a semi-empirical evaluation of the phenomenon might be of interest to workers in mountainous countries. In view of the importance of the process in atmospheric chemistry in general, and especially because of the possible role of activated sodium chloride as nuclei of atmospheric precipitation[4,5], a further study of Junge's data with particular emphasis on this problem was made. Prior to a broader evaluation of the problem and to a laboratory study of the phenomena involved, some results obtained are reported in this communication.

(1) *The Chlorine : Sodium Ratio.* It is well known from observations by Rossby and Egnér[6] that northern air masses carry aerosols of a low chlorine : sodium ratio. Examination of Junge's data shows, however, that this phenomenon which might result in a chlorine : sodium – latitude correlation is smaller in the United States than a strong altitude effect, although it shows in the concentration of nitrate in rain-water (see later). The effect of altitude can be tentatively explained by observing that the intensity of such radiochemical phenomena as may alter sodium chloride aerosols varies nearly exponentially with height[7]. If one assumes that the average yearly horizontal speed of the particle carried by winds does not change considerably from station to station (and therefore that the time which the particle needs to be carried from the shore or an inland salt source to the particular station, is proportional to the distance) the change of chlorine in the air may be expressed as:

$$d\,\mathrm{Cl} = -k\,\mathrm{Cl}\,(\exp \beta h)\,d\,s \tag{1}$$

where s is the distance from the source of particles to the station and h stands for the altitude of the route. s is calculated here from a map and along lines of path straight and orthogonal to Junge's sodium isolines, while both the effective altitude of station (h) and the average altitude of ground-level travel over path s ($\bar{h}$) are used for the height parameter. Values of ($\bar{h}$) are obtained from the map by planimetry of the path. Annual concentrations in gram equivalents × 10^6 × l.$^{-1}$, miles and feet, are used for the chemical species, s and h, respectively.

At the shore or salt-flat point of origin of the particles, $s = 0$; and $\mathrm{Cl} = a\,\mathrm{Na}$, with a obtained directly from ref. 2. Integration of (1) leads to:

$$\log_e\left\{-\frac{1}{s}\log_e\left(\frac{1}{a}\frac{\mathrm{Cl}}{\mathrm{Na}}\right)\right\} = \log_e k + \beta h \tag{1'}$$

It can be seen that (1′) depends on the ratio of components alone and not on their individual concentrations; constants β and k can be obtained by least squares and we find:

$$\beta = (1\cdot_{[illegible]} \pm 0\cdot 9)\,10^{-4};\quad k = (1\cdot_{18} \pm 0\cdot 2)\,10^{-3}$$

It is evident that the true distance an air mass follows may differ substantially from our calculated values of s and that 'individual average speeds' will probably differ. While therefore a relatively large standard deviation of the chlorine : sodium function discussed above ($S.D. = 0\cdot 22$ unit) may well be understood, it appears to be of interest that better consistency is found when parameter s is completely eliminated from the scheme. If altitude alone is assumed to govern the process, then:

$$d\,\mathrm{Cl} = -k\,\mathrm{Cl}\,(\exp k'h)\,d\,h \tag{2}$$

which, following a procedure similar to the one previously described, integrates to:

$$\log_e\left(\frac{1}{a}\frac{\mathrm{Cl}}{\mathrm{Na}}\right) = \frac{k}{k'}\left(1 - (\exp k'h)\right) \tag{2'}$$

When the exponential term in this equation is expanded in series (stopping at the 3rd term) and substituted, (2′) becomes linear in:

$$\frac{\log_e\left(\frac{1}{a}\frac{\mathrm{Cl}}{\mathrm{Na}}\right)}{h} \text{ and } h$$

Constants k and k' can thus be obtained by linear regression; Table 1 gives the results obtained together with standard deviations of the functions computed.

Table 1. Coefficients, Equation of Change of Chloride/Sodium in Rain-water with Altitude (Equation (2′))

Elevation	k	k'	*S.D.* of chlorine : sodium = $f(h)$
h	$(7\cdot_{143} \pm 0\cdot 8)\,10^{-4}$	$(-3\cdot_{[illegible]} \pm 1)\,10^{-4}$	0·156
$\bar{h}$	$(5\cdot_{[illegible]} \pm 0\cdot 7)\,10^{-4}$	$(-2\cdot_{413} \pm 1)\,10^{-4}$	0·144

The expression $\frac{1}{a}\frac{\mathrm{Cl}}{\mathrm{Na}}$ is plotted against $\bar{h}$ in Fig. 1. Since suitable corrections for other factors (such as potassium, latitude, etc.) which might have had an influence on the phenomenon investigated failed to

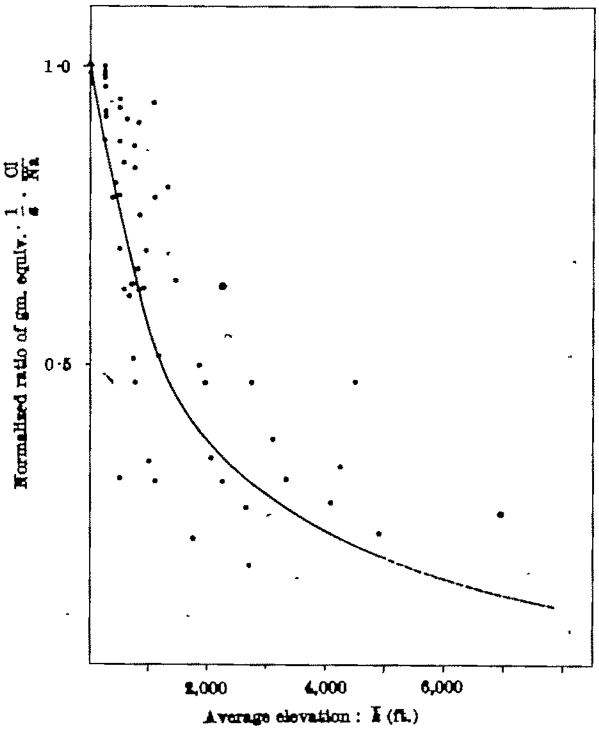

Fig. 1

improve the correlation, and since furthermore equations of type (2) appear to represent the process better than those of type (1) or other patterns considered, it may be thought that in the circumstances prevailing and in view of the large overland distances involved, the transformation of the sodium chloride aerosol must not only be relatively fast but also that it may proceed with a 'pseudo-reversibility'. This could be explained in terms of oxidation of chlorine[8] by factors increasing exponentially with altitude, which would cause a failure of detection of the new species by the chloride test to occur. The oxidized species, after having travelled down-slope, would afterwards be reduced by such atmospheric agents as may prevail at lower heights. An indication of the possibility of such a process may be obtained from the analysis of correlation coefficients between chemical species and altitude over the United States[3]. While in fact an increasing trend of calcium with h is indicated, and sulphate correlates with calcium, an increasing trend between sulphate and chlorine is suggested although both species have negative correlation coefficients with altitude. Second correlation coefficients of sulphate over calcium and chlorine (r_2 = 0·770) and of chlorine over sulphate and h (r_2 = 0·483) are both larger than absolute values of the individual components. We believe that this may be due in part to the oxidation of atmospheric hydrogen sulphide to free sulphuric acid aerosol, by products of oxidation of chlorine.

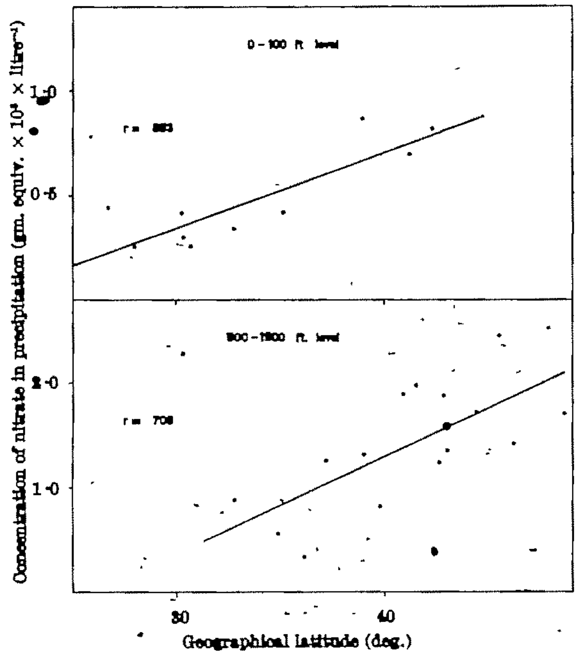

Fig. 2

(2) *Nitrate.* While at higher altitudes nitrate appears almost to be the complement of 'escaped' chlorine, a slight excess of the species over sodium and even over sodium + potassium can be detected at low levels. Plots of nitrate versus latitude for eastern United States are given in Fig. 2; significantly a positive correlation is obtained. The correlation coefficients decrease with altitude and eastward until quite low values for iso-altitudes in the Rocky Mountains are reached. It is possible that the cause of this is to be sought in patterns of atmospheric circulation and in such chemical processes as may be associated with phenomena dependent on geographical or perhaps, rather, geomagnetic co-ordinates.

We are indebted to Prof. V. Caglioti for his encouragement and help and to Prof. G. Fea for his interest in the problems described. Stimulating discussions with Dr. O. Vittori and Prof. D. Fedele are gratefully acknowledged.

METALLURGY

A Symmetrical Fourfold Helical Fracture in Titanium Oxide

DURING the course of experiments on hot pressing powders of various hard, refractory materials, an interesting and apparently inexplicable fracture occurred in a specimen of titanium oxide. The general form of the fracture is shown in Fig. 1. It consists of four helices projecting as shallow cones. The specimen had also broken into four practically equal segments.

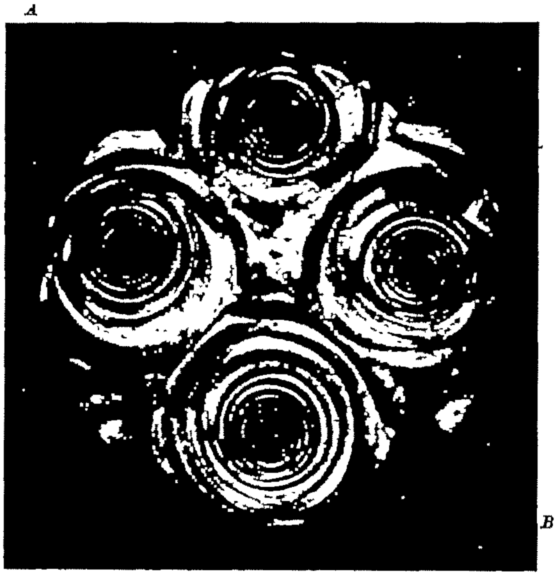

Fig. 1. Fractured surface of titanium oxide. (× 5)

The fracture arose during an attempt to separate the specimen from the cemented tungsten carbide plunger with which it had been pressed and to which it was adhering. Fracture took place almost entirely through the oxide, a layer of which, 0·5–1 mm. thick, remained adhering to the plunger. The second series of fractures, which is perpendicular to the plane of the paper, were normal in appearance. They can be seen in the form of an X with the arms at right angles.

On closer examination of the four helices it can be seen that the tip consists of a very small circle of carbide from the plunger. The helices are of almost identical form and size. Starting at a peak it can be seen that three of the helices are in a clockwise direction; the direction of the fourth is indeterminable. In Fig. 2 one of the helices is shown at a higher magnification.

The specimen was pressed from 98·5 per cent purity titanium dioxide of average particle size 0·2μ in a cemented tungsten carbide die ('Ardoloy *S3*') with a plunger of similar material. A pressure of 10 tons/sq. in. applied for 15 min. at 900° C. was used to produce a specimen ½ in. in diameter approximately ⅛ in. thick. To avoid difficulty in extraction from a cold die, the specimen was ejected while at the pressing temperature into a vessel containing fine aluminium oxide powder heated to 600° C. This could then be slowly cooled to prevent cracking the specimen through thermal shock.

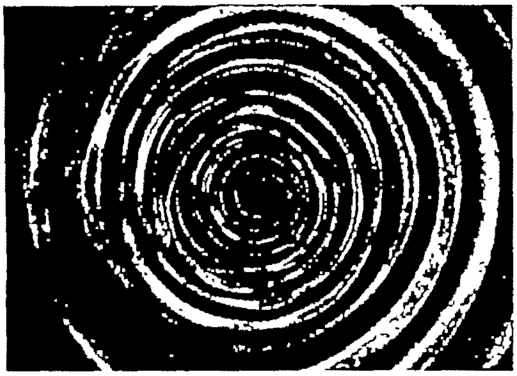

Fig. 2. Spiral fracture. (× 15)

Explanations could possibly be offered to account for the form of fracture shown by the individual segments. The mystifying feature in this case is that such a peculiar form of fracture should occur in a fourfold manner with such a high degree of exactness and symmetry.

The plunger and specimen had been separated by a bending action, the point of pivot being at *A* (Fig. 1) and the point of maximum tension at *B*, that is, in the direction of one of the vertical fractures. The face of the plunger had originally been ground but had become a mat surface through use.

The helical fractures had most likely started at the tip where the carbide adhered. It is possible that this was due to diffusion of material (most likely cobalt) from the plunger into the oxide, since the tips of the cones were also slightly discoloured beneath the level of the adhering carbide. There was no apparent reason, however, for the diffusion to be more prominent in these four symmetrically arranged spots. Internal stresses arising through the rate of cooling and the dissimilar contraction coefficients of the plunger and oxide would no doubt be present apart from the bending stresses, but again could not account for the fourfold symmetry.

Mode of Action of Soluble Matrix Antifouling Compositions

It has been demonstrated by Barnes[1] that the copper leaching-rates of antifouling compositions, based on the same soluble matrix, are proportional to the cuprous oxide content if the total matrix content remains constant.

Work being carried out in this laboratory has shown that the relationship is only correct when the antifouling compositions are stored in almost static sea water between leaching-rate determinations. If the sea water used for storage is agitated, then the leaching-rates of the compositions decrease with increasing agitation until they reach a constant minimum which is independent of the cuprous oxide content.

A possible explanation of these results is that under static conditions of storage the dissolution of copper is confined to particles of cuprous oxide partially embedded in the surface of the matrix; these particles produce a concentrated surface layer of copper ions which prevents any diffusion of copper ions from the matrix. Agitation reduces the ionic concentration of copper in the surface layer and also may remove all the particles of cuprous oxide exposed at the surface.

Under such conditions the leaching is due entirely to the diffusion of copper ions through and from the whole of the surface of the matrix (apart from areas occupied by fillers): it is independent of the cuprous oxide content and the rate depends mainly on the rate of reaction of the matrix. Increased agitation has little or no effect on the leaching-rate provided the compositions are suitably pigmented to reduce mechanical erosion to a minimum. By increasing the temperature of the agitated sea water it has been shown that it is possible to increase the rate of solution of the matrix until it exceeds the rate of diffusion of the copper ions.

Under these conditions the leaching-rates again become proportional to the cuprous oxide contents

These observations are considered to have an important bearing on the study of the performances of antifouling compositions on ships under way and in dock.

CHEMICAL ENGINEERING

Control of Reaction Rate in Dust Flames

Ever since Nusselt[1] introduced the boundary layer concept, about forty years ago, for calculating rates of heat and mass transfer to a spherical particle, it has been universally accepted (without proof) by subsequent theoretical work (see ref. 2) that the reaction-rate of particles in a dust flame is determined by the rate of supply of oxygen through a diffusional boundary layer surrounding the particles. That this might not in fact be so was first suggested[3] about five years ago, the alternative proposition being that the rate control was chemical, not physical; the source of the implied error is attributed to the misinterpretation of reaction data in terms of diffusion instead of chemisorption which, according to Brunauer[4], has been a common mistake in the past. Support for the alternative hypothesis, however, has now been provided by analysis of experimental results obtained recently from an anthracite flame.

The experimental furnace or reactor has been described in outline elsewhere[5]; the flame generated by it may be regarded as a vertical cylinder, 18 in. in diameter and 15 ft. high, in which the particles travel paraxially downwards. The residual coke, mainly carbon formed by expulsion of volatiles, is brought up to temperature by burning these volatiles in primary air; the reaction we are chiefly interested in is then initiated by the 'instantaneous' introduction of secondary air at an appropriate point, and the subsequent reaction is followed down the furnace by solid sampling. Since anthracite is non-caking, complications from swelling are eliminated.

For theoretical analysis the material is assumed to be pure carbon. On the respective hypotheses of physical (diffusional) and chemical reaction control, the equations for specific reaction-rate (R_s) may be written respectively:

$$R_s = k_D/d\ ;\quad R_s = k_c \qquad (1a,b)$$

where d is the particle diameter; and the factors k_D and k_c are both proportional to the concentration of the main stream of oxygen[6], and are both known functions of temperature (T). k_D contains the diffusion coefficient and therefore follows a T^2 law; and k_c contains the Arrhenius factor, $\exp(-E/RT)$. In the past, it has been assumed that k_c has a much greater temperature coefficient than has k_D. The source of this possible error was the wrong choice of value for E, the value of 40,000 cal. generally used being that for the decomposition of the adsorbed oxide film[7]. This decomposition process, however, only controls the reaction at low temperatures (less than 1,000° C.). At flame temperatures (greater than 1,000° C.) the rate of chemisorption becomes important, and if the assigned[3,4,5] value of the activation energy for this, namely, 4,000 cal., is valid, then k_c also approximates closely to a T^2 law.

Appropriate integration of equations (1) for a single particle in an infinite atmosphere gives the burn-out time (t_b) as a function of initial diameter (d_0); respectively, we get:

$$t_b = K_D.d_0^2\ ;\quad t_b = K_c.d_0 \qquad (2a,b)$$

where the burning constants K_D and K_c may be calculated from diffusion theory and kinetic theory respectively; their values are found to be of the order of 1,000 and unity. The validity of equation (2a), both with respect to the square law and to the value of the constant, has now been confirmed by experiments[8] on captive coal particles suspended in a radiation and low-intensity convection field, the particle sizes ranging from 300 microns to 4 mm.

In flames, however, a limited air supply increases the burning times. Following Nusselt[1] and others[10], the multiplying factors (F_D and F_c) for the two cases have been shown[9] to be calculable functions of excess air alone. These various functions have been

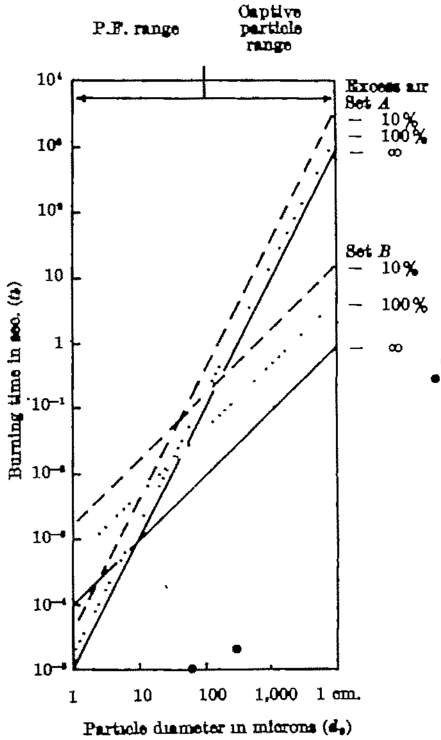

Fig. 1. Comparison of calculated burning times in a flame, at 1,500° C., on the hypotheses of diffusional and chemical reaction control respectively (hypothetical carbon flame). Set *A*, physical control: $t_b = F_D \cdot K_D \cdot d_0^2$; set *B*, chemical control: $t_b = F_c \cdot K_c \cdot d_0$

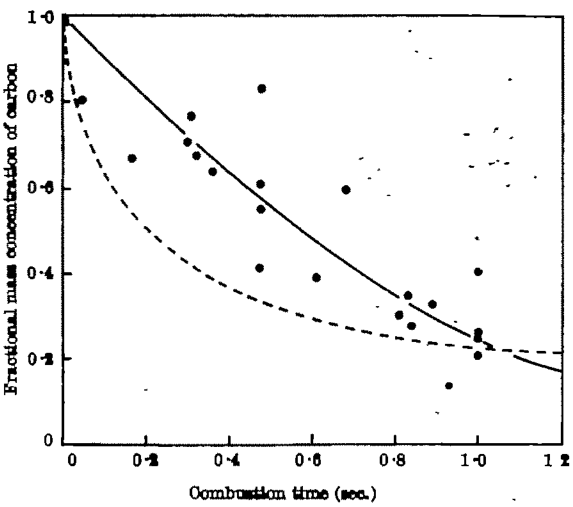

Fig. 2. Decay of carbon concentration in a dust flame with time. Comparison of experimental values (●) with predicted values assuming: (i) diffusional rate-control (dotted line); (ii) chemical rate-control (full line)

calculated[10], and Fig. 1 shows the burning times predicted from the two theories for a carbon dust flame at 1,500° C. at three levels of excess air: 10 per cent, 100 per cent and infinity (single particle). From this it is clear that, if the assumptions made are valid, we have two regimes as follows: (i) the 'captive particle' range of 100 microns to 1 cm., over which the diffusional processes have been proved to be dominant when the convection field is weak; and (ii) the pulverized fuel range of 1–100 microns, inside which, in real flames (less than 100 per cent excess air), the diffusion mechanism is unimportant.

The existence of the first regime in weak convection fields is now established; its continued existence in strong convection fields is at present under experimental examination. The question immediately at issue here is: Does the first regime extend also into the pulverized fuel range, or is it superseded by the second regime, as suggested by argument from Fig. 1? To test this, predictions have been made from the alternative theories derived as special cases of a general theory (Siddall, R. G., private communication) and these have been compared with measurements from the furnace. The starting equations used were in effect (1*a*) and (1*b*), but integrated to predict the time required to burn to varying degrees of incomplete combustion, the effect of distribution of particle size being allowed for in this. The results of these calculations are shown in Fig. 2. In this, fractional mass concentration has been plotted against time for (i) diffusional control (dotted line), and (ii) chemical control (full line); the final fit was adjusted by means of a somewhat arbitrary constant the value of which is difficult to calculate from absolute theory, but the shapes of these curves are determined by the diameter function which is predicted. For the experimental comparison, the full circles are the experimental points.

In our opinion, the chemical control theory gives a much better fit to the experimental results than does the physical control theory. While, therefore, this is not yet conclusive, we suggest that surface reaction at high temperatures plays a much bigger part than previously imagined, and it therefore deserves much greater attention than has been accorded to it in the past.

OCEANOGRAPHY

Alleged Occurrence of the Perchlorate Ion in Sea-Water

In a recent communication, Baas Becking, Haldane and Izard[1] claimed to have found up to 100 p.p.m. of perchlorate in sea and ocean waters, and between 100 and 1,000 p.p.m. in estuarine and inshore waters. They have suggested that this perchlorate is formed from chloride in the water by oxidation, and that the formation of perchlorate in this manner will reduce the chlorinity of the water to the extent of up to the second decimal per mille.

In view of this suggestion, we have re-investigated the occurrence of perchlorate in sea-water, using a new analytical method. The water sample is treated with potassium perrhenate and tetraphenylarsonium chloride; the precipitate of the slightly soluble tetraphenylarsonium perrhenate co-precipitates perchlorate from the sample. The dried precipitate is formed into a disk with potassium bromide and the amount of perchlorate is determined by measuring the optical density of the disk at 9·12µ. The method is sensitive to about 0·03 p.p.m. of perchlorate ion and has a coefficient of variation of about 9 per cent with 1·0 p.p.m. perchlorate ion. Neither periodate nor the ions normally present in sea water interfere.

We have examined surface and deep-water samples from 25 stations in the Arctic Ocean, North Atlantic, English Channel, Mediterranean, Indian Ocean, Red Sea and Persian Gulf. In no case have we been able to detect any trace of perchlorate. These negative results are confirmed by the observations of Klemperer[2] that the addition of as little as 0·05 p.p.m. of perchlorate to sea water reduces the rate of uptake of iodine by *Fucus ceranoides* by about 60 per cent.

It is suggested that the results obtained by Baas Becking *et al.*, using methods based on methylene blue, were in error owing to the interfering effects of many other ions, particularly sulphate[3] and chloride, and to the generally capricious nature of this reagent.

We thank Mr. J. Berkeley for making the infra-red measurements.

CHEMISTRY

Covalent Super-Exchange in Solid State Physics

MAGNETIC coupling of next-to-nearest neighbours through a non-magnetic anion (super-exchange) has been explained by Anderson[1] by considering 'excited states' in which a single electron in a p-orbital of the anion is transferred to one of the neighbouring cations. Goodenough and Loeb[2] have emphasized correctly that such interactions are essentially covalent and have given the name 'semi-covalence' to Anderson's one-electron transfer. As stressed by Goodenough and Loeb, the increase in Curie or Néel temperatures in series such as MnO-FeO-CoO-NiO, or MnO-MnS-MnSe-MnTe, is evidence for the part played by covalence in magnetic coupling.

Anderson's theory leads to the prediction that super-exchange should be antiferromagnetic if the paramagnetic ion has its original d-shell half-full or more (manganese, iron, cobalt, nickel, copper) and ferromagnetic otherwise (titanium, vanadium, chromium). There are many exceptions to this rule, as shown in Table 1.

Table 1. FERROMAGNETIC AND ANTIFERROMAGNETIC COMPOUNDS OF ELEMENTS IN FIRST TRANSITION SERIES

A, Antiferromagnetic; F, ferromagnetic; (n), number of electrons in covalent structure

* Only electrons in M-S bonds counted.

Numbers in parentheses in Table 1 refer to the number of electrons participating in covalent bonding; that is, the number of electrons in molecular orbitals surrounding an anion. Inspection of these numbers indicates that antiferromagnetism tends to occur when n is even, whereas ferromagnetic coupling occurs when n is odd.

To determine the number n, one must first consider the effect of crystal-field splitting on the $3d$-levels of the paramagnetic cation. Let n' be the number of electrons in the upper level (for example, 2 for manganese ions, 1 for chromium ions (Cr^{3+}), in an octahedral field). If p is the co-ordination number of the cation and q that of the anion, $n = n'\frac{q}{p} + n''$, where n'' is the number of valence electrons of the anion. It makes no difference whether n'' includes s-electrons or not, as the number of s-electrons is even. Thus for manganese sulphide, $p = q = 6$, $n' = 2$, $n'' = 8$ (or 6), $n = 10$ (or 8) and is even. In chromium sulphide (CrS), $n' = 1$, $n = 9$ (or 7) and is odd. Expressed in a different manner, n' is the number of $3d$-electrons of the cation participating in the formation of hybrid orbitals, the nature of the latter being deduced from the symmetry of the anionic arrangement around a cation (for example, d^2sp^3 in octahedral manganese sulphide, d^3p^3 in the distorted trigonal antiprism of α-Fe_2O_3).

Although no rigorous treatment can be carried out at this moment, a simple argument may suggest why the sign of super-exchange interaction depends on whether n is even or odd. Consider manganese sulphide, in which both cation and anion are in octahedral co-ordination. Both can use d^2sp^3 hybrid orbitals, and six bonding and six antibonding molecular orbitals can be formed around each sulphur. These orbitals contain 10 electrons, and so with respect to a fully covalent structure the compound is deficient in electrons. Four molecular orbitals will carry two electrons each; charge correlation requires that the two remaining electrons be as far apart as possible, that is, 180°. These will go into molecular orbitals on opposite sides of the anion, thus accounting for the large angle characteristic of super-exchange. These two molecular orbitals are not fully orthogonal because of overlap of the orbitals of the cation on either side of the central anion, and they may thus be considered to form two orthogonal three-centred orbitals of slightly different energies. The ground-state will be such that the two electrons in the bridge occupy the lowest of the 3-centre orbitals with spins antiparallel; these electrons in turn interact with the remaining t_{2g} electrons on the adjacent cations (as implied in ionic-covalent resonance), which will be coupled antiferromagnetically. The single electron in the 3-centre orbital of chromium sulphide must lead to ferromagnetic coupling.

A similar analysis can be carried out for other substances listed in Table 1. More complicated oxides (for example, ferrites) present an additional problem in that n is commonly not an integer (9·75 in Fe_3O_4). For fractional numbers between 9 and 10, one may hesitate to predict the sign of super-exchange; possibly in such cases a small amount of direct exchange between next neighbours is the determining factor. For example, chromium oxide (Cr_2O_3) is antiferromagnetic although it might be expected to be ferromagnetic ($n = 8½$). Neutron diffraction reveals ferromagnetic coupling between cations at large distances and at large Cr-O-Cr angles; only interactions at shorter distances and through smaller angles (hence presumably not super-exchange) are antiferromagnetic. In dioxides with the rutile structure (vanadium, chromium, manganese dioxides), further complications arise from the possibility of extensive π-interaction between oxygen p (the oxygen is in trigonal planar hybridization) and metal t_{2g} orbitals. It is worth noting that the present arguments predict that a solid solution of vanadium oxide (VO_2) and manganese dioxide in the ratio 1 : 1 would have the same electron number as ferromagnetic chromium oxide, and should accordingly also be ferromagnetic, although the two end-members are both antiferromagnetic.

Atomic Absorption Spectrophotometric Determination of Molybdenum and Strontium

RECENT work reported by Menzies[1] and Robinson[2] has suggested that atomic absorption flame methods[3,4] are not applicable to the determination of molybdenum and that the limit of strontium determination lies between 2 and 10 p.p.m. in solution.

Using a 10-cm. air-acetylene burner, a scale expansion device (suggested by Dr. J. B. Willis) and a modulated single-beam system[5], it has been found that the limits of estimation of molybdenum and strontium in solutions free from interfering ions are about 0·5 and 0·05 p.p.m. respectively. Molybdenum 3132 Å. (a^7S–y^7P°) was the strongest in absorption of the nine absorbing molybdenum lines found. Strontium measurements were carried out on strontium 4607 Å. The gain in sensitivity for strontium over those previously reported is a direct result of stability of hollow cathode emission, the use of a long burner and the use of an expanded scale on the measuring unit reading 0–20 per cent absorption over full scale. The determination of molybdenum was achieved by adjustment of the air and acetylene pressures to give reducing conditions in the flame and passage of the beam from the hollow cathode discharge tube through the flame at a point just above the cone of unburnt gases.

The concentration of free ground-state atoms of molybdenum in the flame was found to be critically dependent on the proportions of air and acetylene. No perceptible absorption resulted from spraying a 50 p.p.m. molybdenum (ammonium molybdate) solution into an air-rich flame, whereas adjustment of the proportion of air to acetylene to give a flame in which yellowing due to incandescent carbon particles was just visible at the base gave an absorption of 35 per cent. Provided that the beam from the hollow cathode tube was confined to the lowest possible level in the flame, no great gain in sensitivity resulted from the use of a highly luminous flame. Despite this dependence on reducing conditions, the presence of an oxidizing agent in the sample solution did not cause serious depression of molybdenum absorption (compare cols. 3 and 4, Table 1). The presence of the large excesses of extraneous elements in the samples examined had a greater effect than did nitric acid (compare cols. 4 and 5, Table 1), but this effect was not so great as to cause difficulty in analysis due to loss of sensitivity.

The results in column 5 of Table 1 were obtained by use of the 'addition' method. This procedure has been used in arc emission determination[6,7] of trace elements in samples of widely variable major element composition. However, poor precision and uncertainty regarding linearity of the relationship between emitted intensity and concentration impairs its value in arc analysis. Provided the equation of a non-linear curve is known, the use of the addition method is possible, but tedious.

Table 1. Concentrations of molybdenum in samples of molybdenized superphosphate (nominally 1·5 oz. molybdenum trioxide per cwt.) and stainless steel as calculated from atomic absorption analysis against standards in water, in 0·82 *N* nitric acid and by the 'addition' method. The analyses were carried out directly on portions of 200-ml. final volumes of nitric–hydrochloric acid solutions prepared from the samples

Sample	Weight taken (gm.)	Apparent molybdenum concentration using		Molybdenum concentration by addition method (per cent)
		Standards in water (per cent)	Standards in nitric acid (per cent)	
Superphosphate (1)	8·42	0·0317	0·0356	0·0575
(2)	10·0	0·0366	0·0412	0·0555
(3)	10·0	0·0366	0·0412	0·0526
Stainless steel (1)	2·930	0·159	0·179	0·266
(2)	2·933	0·171	0·192	0·278

By taking three equal aliquots of a sample solution, adding equal volumes of water to one and solutions containing known concentrations of the analysis element to the other two, then analysing all three using the apparatus described, it was found that the relationship between percentage absorption and concentration was linear up to about 15 per cent absorption. This test has been carried out for molybdenum in the samples cited in Table 1, for strontium in ammonium chloride extracts of soils and in nitric–perchloric–sulphuric acid digests of plant material and for calcium in solutions for microbiological culture.

The addition method was found essential to the analysis of plants for strontium because measurements on synthetically prepared solutions indicated that the interferences would be so difficult to control that the results of analysis against orthodox standards would be unreliable. Advantage may be gained from the general application of the addition method to atomic absorption analysis because, in using it, both sample and 'standard' are measured under exactly the same conditions of viscosity, surface tension and chemical interference and because modulated atomic absorption apparatus cannot measure anything but atoms of the analysis element in the flame.

Although insufficient sensitivity has been attained, as yet, in the direct atomic absorption analysis of solutions from plants and soils for molybdenum, the results in Table 1 indicate that advantages can be gained from its application to such analytical fields as those of the fertilizer and metallurgical industries. The specificity of the atomic absorption method employing a modulated system for measurement of the element sought gives it obvious advantages over flame emission methods in the analysis of soils, plants, bones and the like for natural strontium in 'fall-out' studies.

The results for molybdenum suggest the possibility of using reducing flame conditions to make possible atomic absorption analysis for other elements. They also suggest that further gains in sensitivity may result not only from designing burners to give high-temperature flames, but also from designing them to produce highly reducing conditions in the flame.

The apparatus used and the results of these and further investigations will be described in detail elsewhere.

Determination of Nickel and Cobalt by Atomic Absorption

In the atomic absorption method of analysis, first described by Walsh[1], the solution to be analysed is sprayed into a flame, and with a hollow-cathode lamp which emits the line spectrum of the element being determined as the light source, the absorption of light by atoms of the element is measured at a characteristic wave-length.

To realize the full potentialities of the method, it is obviously important that the strongest absorption line be used. As at the temperature of commonly used flames all but a small proportion of the atoms are in the ground-state, only lines due to absorption by unexcited atoms need be considered, and of these lines it is usually assumed that the strongest absorption line will correspond to the strongest emission line. I have pointed out that while this is so in the simple spectra of the elements in Groups I and II, it is not necessarily the case in the more complex spectra of the heavier elements, and that as oscillator strengths for the various lines of these elements are generally not known, it is necessary to determine experimentally which line is the strongest in absorption[2]. Results were given for manganese and iron, showing that for these elements the strongest absorption lines were at 2794·8 Å. and 2483·3 Å. respectively.

The spectra of nickel and cobalt have now been investigated by the methods described previously. It has been found that the strongest absorption line for nickel is at 2320·0 Å. ($a^3F_4 - y^3G^\circ_5$), the absorption at this wave-length being about fifteen times that at 3415 Å., the wave-length of the strongest emission line. For cobalt, the strongest absorption line is at 2407·2 Å. ($a^4F_{4\frac{1}{2}} - z^4G^\circ_{5\frac{1}{2}}$), and this line is about fifty times as sensitive in absorption as is the strongest emission line at 3527 Å.

When these lines are used, the atomic absorption method can usefully be applied to the determination of nickel and cobalt, the sensitivity obtained being about the same as that already reported for iron.

I thank Mr. O. E. Clinton for his assistance with this work, full details of which will be reported elsewhere.

BIOCHEMISTRY

Steric Factors affecting the Specificity of Polyglycosidases

The marked substrate specificity exhibited by enzymes has been related to a steric affinity between the molecule attacked and the attacking enzyme[1]. According to this concept, proper orientation of the substrate in the vicinity of the enzyme permits formation of an activated intermediate in which several points of contact may be established.

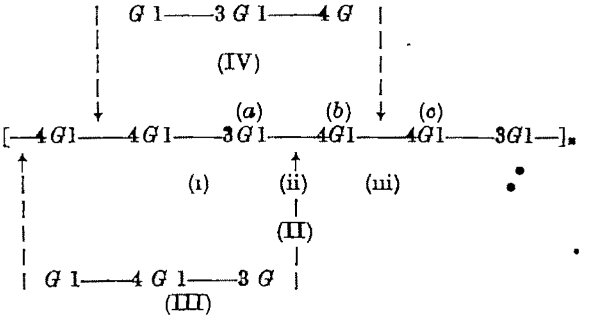
Enzymes which hydrolyse simple glycosides exhibit extremely high specificity for the glycosyl radical of the molecule, whereas the structure of the aglycone group usually is important in a quantitative, rather than qualitative, sense[2,3]. Glycosidases that degrade polysaccharides (I) appear to show high specificity for

$$[\text{—}\overset{(a)}{xG1}\text{——}\overset{(b)}{xG1}\text{—}]_n$$

(I)

a particular type of linkage, as well as glycosyl unit. In evaluating such specificity, the enzyme is tested usually with several polysaccharides each of which contains only one type of sugar component and linkage (or as close as possible to this ideal); this procedure has become general since few polysaccharides of more complex structure are characterized in sufficient detail to be suitable as enzyme substrates. Cellulase, for example, degrades polymeric chains in which β-D-glucopyranose units are linked through positions-1 and 4 (I, G = D-glucopyranosyl; X = 4) but not when the linkages are β-(1→3), α-(1→4), etc., and is regarded as a β-(1→4)-poly-D-glucopyranosidase. In common usage, this terminology refers to the linkage cleaved, and implies that its position of attachment to unit I(b) has an important bearing on specificity. However, the glycosyl unit (a) is itself attached to a third unit (through the X-hydroxyl group), and the location of this linkage also might be expected to affect specificity through its influence on the stereochemistry of (a). Clearly, the relative importance of these steric factors is difficult to assess with polysaccharides of homogeneous structure. Recent observations[4] on the enzymolysis of a polysaccharide that contains mixed types of linkages suggest, however, that such questions should be taken into account in classifying polyglycosidases.

The polysaccharide examined is a soluble D-glucan from oats[5,6], the structure of which is represented[4,6] mainly by II, that is, a linear chain of β-D-glucopyranosyl units in which two (1→4) linkages (ii) and (iii) alternate repeatedly with a (1→3) linkage (i). Two different enzyme preparations have been found to degrade the glucan rapidly and extensively under conditions expected to minimize trans-glycosidation side-reactions. One of the enzymes has been classified as a β-(1→3) D-glucosidase, since it shows high specificity for laminarin and only low activity on other substrates tested[7]. With this polyglycosidase, the major product obtained from the oat glucan is trisaccharide III[4,6], showing clearly that hydrolysis is preferential for linkage (ii), that is, the glycosidic bond of a β-D-glycosyl unit (a) attached through positions-1 and -3 to adjacent units, rather than a β-(1→3) linkage (i). (In laminarin, of course, most of the glycosyl units possess this type of 1,3-relationship.)



The second enzyme used, a cellulase from *Streptomyces* sp. *QM B*814[8], degrades the glucan mainly to trisaccharide IV[4,6], showing that the hydrolytic action of this enzyme is preferential for linkage (iii). Now, linkages (ii) and (iii) of the polysaccharide are both of the β-(1→4) type, but glucosyl unit (*a*) is substituted at position-3; glucosyl unit (*c*) is substituted at position-4 but is attached to position-3 of an adjacent unit. Hence only glucosyl unit (*b*) is equivalent to a unit in a cellulose chain. The ready attack by the *Streptomyces* cellulase at this point indicates that the → 4-β-D-glucose relationship is at least as important for the enzyme action as is the β-D-glucose-(1→4) relationship.

These considerations are subject, of course, to the usual qualification that the enzymes used may not be pure—a difficulty which at present cannot be settled. However, they direct attention to the possibility that the current view of polyglycosidase stereospecificity is insufficiently broad. It may thus be desirable to regard cellulases, for example, as exhibiting (4→)-β-(1→4)-D-glucopyranosidase activity in recognition of the fact that the substrate attacked contains a *4-substituted* β-D-glucopyranosyl unit, and not a free β-D-glucopyranosyl unit. Such a term would be particularly apt for several known cellulases that degrade cellulose but do not attack cellobiose. The latter, it will be noted, contains the β-(1→4) linkage but the glycosyl unit itself is not substituted at position-4. Similar considerations could apply for other polyglycosidases (for example, β-amylases) that produce oligosaccharides, but not monomer, from polysaccharides.

We are grateful to Dr. E. T. Reese for permission to quote unpublished data from collaborative studies.

'pH-Chromatography' of some Amphoteric Antibiotics

'*p*H-CHROMATOGRAPHY' is a paper chromatography method which can be used for simultaneous determination of the ionic character of antibiotics and of suitable *p*H values for their extraction[1]. The *p*H-chromatogram of an antibiotic is obtained by chromatographing on a series of strips of chromatographic papers buffered to *p*H values from 2 to 10. For the development of the strips by the ascending technique an organic solvent saturated with water is used. A suitable solvent is chosen by determining the solubility of the antibiotic being studied by paper chromatography[2]. In our reports on the *p*H-chromatography of antibiotics[1,3] we described three types of *p*H-chromatograms, depending on the ionic character of antibiotics:

(1) R_F values of *p*H-chromatograms of antibiotics of acidic nature give *S*-shaped curves, the maxima of which lie in the acidic range; with increasing *p*H values the R_F values diminish.

(2) The R_F values of *p*H-chromatograms of antibiotics of basic character give S-shaped curves of a reverse character; the maximum of the curves being in the basic and the minimum in the acidic range, respectively.

(3) *p*H-chromatograms of neutral antibiotics have practically the same R_F values along the whole range of *p*H values, giving a straight line parallel with the starting points.

The optimal *p*H for extraction of acidic or basic antibiotics is in the region of the maximal R_F value; the most suitable *p*H for re-extraction into water being that *p*H where the R_F on the *p*H-chromatogram is smallest.

We use *p*H-chromatography in seeking new antibiotics and sometimes obtain *p*H-chromatograms of a different type, which have so far not been described. The R_F values of this type of *p*H-chromatogram increase stepwise in the range of lower *p*H values and after reaching a certain maximum they begin to diminish. These compounds behave as bases from *p*H 2 to the point of their maximal R_F, and from this point on up to *p*H 10 they behave as acids. We presume that compounds belonging to this group are amphoteric.

We have run *p*H-chromatograms of some known amphoteric antibiotics, chlortetracycline, oxytetracycline, tetracycline, and mycostatin (nystatin) to verify this. The *p*H-chromatography of all these antibiotics was performed by the ascending technique in *n*-butanol saturated with water, the spots being detected microbiologically.

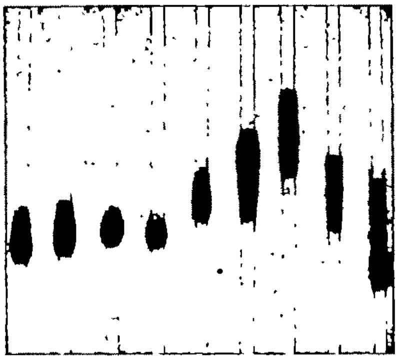

Fig. 1. *p*H-chromatogram of tetracycline in *n*-butanol saturated with water

In Fig. 1 a *p*H-chromatogram of tetracycline is presented. The R_F values of the spots increase stepwise up to *p*H 8, and successively diminish in the region of higher *p*H values.

The dependence of the R_F values of tetracyclines on *p*H values is depicted in Fig. 2. The R_F curves of chlortetracycline and tetracycline have a similar character and the maxima of both lie in the region of *p*H 8. The maximum of the R_F curve of oxytetracycline is in the region of *p*H 6, and the character of this curve is different from the character of the curves of previously mentioned antibiotics. We presume that the character of the curves is to some degree a function of the structure of the compounds studied, chiefly of the number of 'acidic' OH-groups present, chlortetracycline and tetracycline having five, and oxytetracycline six, OH-groups, respectively.

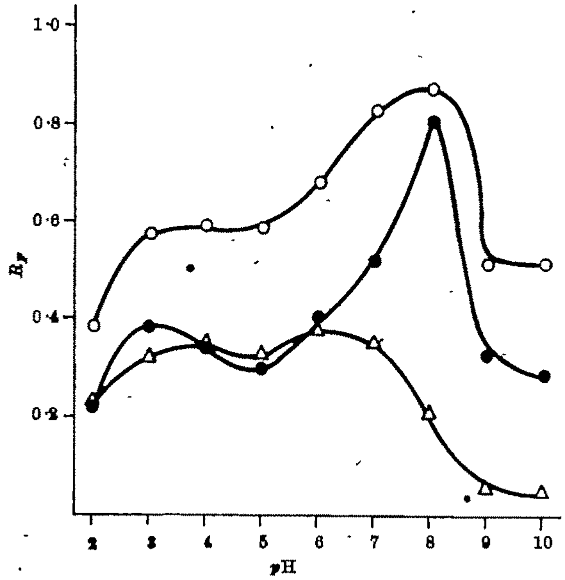

Fig. 2. Dependence of the R_F of tetracyclines on pH; solvent: *n*-butanol saturated with water. ○, Chlortetracycline; △, oxytetracycline; ●, tetracycline

In Fig. 3 the dependence of the R_F values of mycostatin on *p*H is shown; the curve having its maximum in the region of *p*H 8.

In all the cases presented the curves are not absolutely smooth; for example, they do not have the smooth character of the curves of acidic and basic antibiotics. Up to now we do not know the cause of this phenomenon; but we presume it could be caused by different chemical structure of the compounds studied.

We have also analysed by *p*H-chromatography the antibiotic *cycloserine* (oxamycin), the data of the ionic character of which differ in the literature. According to Harned *et al.*[4] this compound is a weak acid, whereas others[5] consider this compound to be amphoteric. The *p*H-chromatogram of this antibiotic (Fig. 4) proves it to be amphoteric.

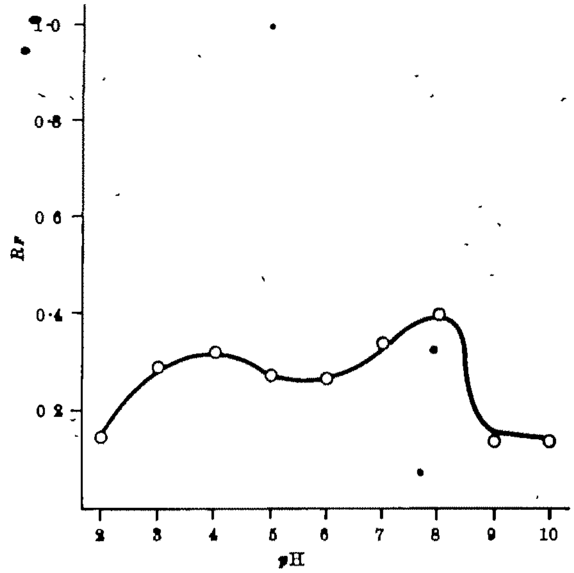

Fig. 3. Dependence of the R_F of mycostatin on pH; solvent: *n*-butanol saturated with water

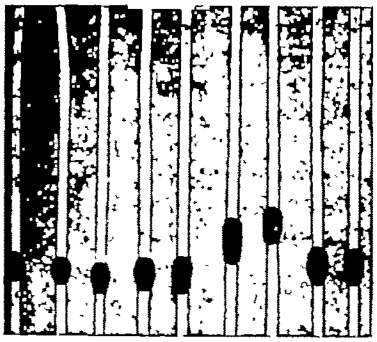

Fig. 4. pH-chromatogram of cycloserine in methanol

By the method described here, unidentified and, up to now, not even concentrated antibiotics can be divided into four groups according to their ionic character, that is, into acids, basic, neutral, and amphoteric compounds, and the suitable *p*H values for their extraction and eventual re-extraction into water can be determined. As the optimal *p*H value for the extraction of acidic and basic antibiotics lies in the range of that *p*H value where the R_F on the *p*H-chromatogram is greatest[1], we can presume that the same would be valid also for amphoteric antibiotics. Similarly, the region of the smallest R_F values indicates the most suitable *p*H for the re-extraction from the organic solvent into water.

We are of the opinion that the *p*H-chromatographic method can be used also for the determination of the ionic character of other compounds of biological origin and for the determination of suitable isolation procedures of these compounds.

Interaction of Actinomycin with Deoxyribonucleic Acid

IN previous papers, Kawamata *et al.*[1,2] have reported the carcinogenic effect of actinomycin. In the course of investigating the mechanisms of action of actinomycin, evidence was obtained that this antibiotic shows a specific interaction with deoxyribonucleic acid. In the following experiments actinomycin *S* was used[3].

In order to examine the relation between nucleic acids of bacteria and actinomycin *S*, the extracts obtained from bacteria cultured in the presence or absence of actinomycin *S* were subjected to zone electrophoresis.

Bacillus subtilis strain NRRL-*B*558 was grown on a salt–glucose plus casein acid hydrolysate medium by shaking at 35° C. After culture for 6 hr. 10 μgm. of actinomycin *S* was added to the culture medium and incubated further for 1 hr. Then the bacteria were harvested and washed twice with chilled, distilled

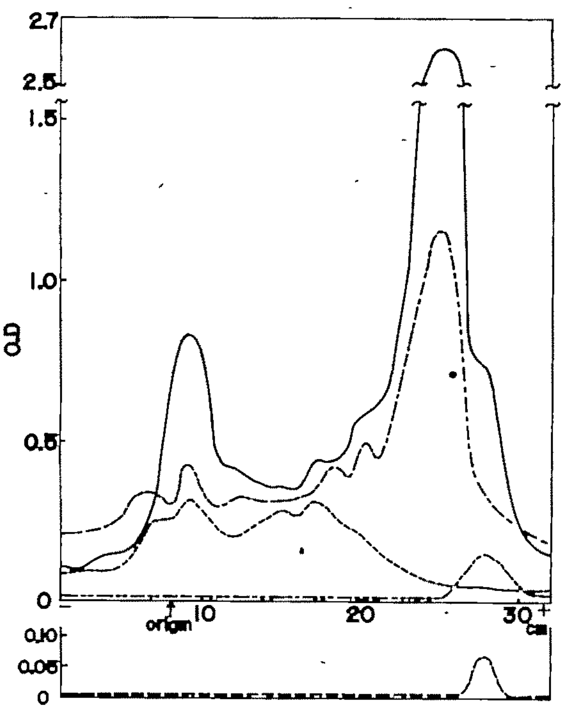

Fig. 1 Starch electrophoresis patterns of an extract of *B. subtilis*. Bacteria were grown at 35° C. with shaking in salt–glucose plus amino-acid medium. 10 μgm./ml. actinomycin *S* was added after 6-hr. culture. (———), ultra-violet absorption at 260 mμ; (– – – – – – –), Folin's reaction at 750 mμ, (— – — – —), orcinol–hydrochloric acid reaction at 660 mμ, (– – – – – – – –), diphenylamine reaction at 600 mμ, (— — — —), spectral absorption of actinomycin *S* at 440 mμ

water and an extract was prepared in 0·1 *M* phosphate buffer solution by grinding the precipitate of bacteria with alumina. Starch electrophoresis was performed in *p*H 8·8 borate buffer, ionic strength 0·1. The runs were made at 5° C. with constant current of 3 m.amp./cm.[2] for approximately 17 hr. The starch was then cut into 1 cm. sections, and each section was eluted with distilled water. The eluates were used for subsequent analyses. Total nucleic acid was estimated by readings of optical density at 260 mμ. The amounts of protein, ribonucleic acid and deoxyribonucleic acid were estimated by the Folin, orcinol, and diphenylamine methods respectively. Actinomycin *S* was estimated by readings of optical density at 440 mμ.

Results of analyses of a starch electrophoresis are shown in Fig. 1. Amounts of substances are plotted against distance travelled from the origin towards both electrodes. Actinomycin *S* was found to be distributed corresponding to the fraction of deoxyribonucleic acid. The same pattern was obtained when actinomycin *S* was subjected to zone electrophoresis together with the extract prepared from bacteria cultured in the absence of actinomycin *S*. Actinomycin *S* alone, however, travels to the cathode. Such an interaction was observed between actinomycin *S* and deoxyribonucleic acid prepared from calf thymus.

Table 1. Reversing Effect of Deoxyribonucleic Acid on Growth Inhibition of *B. subtilis* NRRL-*B558* by Actinomycin *S*

Actinomycin *S* in medium (μgm./ml.)	Time incubated (hr.)	Turbidity E_{530}			
		Deoxyribonucleic acid of calf thymus		Ribonucleic acid of yeast	
		none	0·05%	none	0·05%
0	0 2 4 6 8	0·055 0·075 0·240 0·570 0·700	0·055 0·072 0·250 0·560 0·730	0·040 0·072 0·370 0·700 0·790	0·040 0·060 0·300 0·720 0·810
0·01	0 2 4 6 8	0·055 0·060 0·075 0·085 0·090	0·055 0·075 0·240 0·560 0·710	0·040 0·055 0·075 0·080 0·090	0·040 0·082 0·107 0·120 0·150

Moreover, the inhibition of bacterial growth by actinomycin *S* was virtually abolished in the presence of thymus deoxyribonucleic acid in the medium, but not of yeast ribonucleic acid. The results are shown in Table 1.

In considering the fact that actinomycin has a potent anti-cancer activity, as well as marked carcinogenic effect in mice, the interaction shown between actinomycin *S* and deoxyribonucleic acid might play an important part in the mechanism of action. The mode of this interaction is now under investigation.

It is hoped that a full account of this work will be published elsewhere.

Biosynthesis of Sucrose by Preparations from Potatoes stored in the Cold and at Room Temperature

Perhaps the most pronounced and consistent metabolic response of potato tubers to stress situations, such as low and high temperatures, loss of water, and ionizing radiation, is the accumulation of sugars, especially sucrose. Although the relationship of sugar content to the so-called non-enzymatic browning of processed potato products has been amply documented[1], the biochemical events which create a milieu favourable to accumulation of sucrose are unknown. Conceivably, this increase in sucrose could arise as the result of changes in amounts of enzymes involved in sugar formation from starch, as compared with those involved in removal of sucrose.

Of these enzymes, the one most likely to be involved directly in sucrose metabolism would seem to be uridine diphosphoglucose → fructose-transglycosylase, first described by Leloir and co-workers[2] in wheat germ, maize germ, potato sprouts, pea seeds, beet shoots, etc., and demonstrated more recently in sugar beet leaves[3] and in soybeans and broad beans[4]. Although a net increase of sucrose has been demonstrated when fructose or glucose is administered to potato disks[5] and when potato tuber homogenates are incubated in the presence of glucose-1-phosphate, fructose, and dextran sucrase[6], demonstration of the presence of uridine diphosphoglucose → fructose-transglycosylase in potato tubers has not been reported.

We have now found that the potato tuber is a rich source of sucrose-synthesizing enzyme (Table 1). The enzyme fractions were prepared from 600 gm. of peeled Washington Russet tubers previously stored for 12 days at 25° C. or 2° C. The tubers were homogenized with 30 ml. of 0·1 *M* phosphate buffer of *p*H 7·0. After filtration through 'Celite', the filtrate was made 0·7 saturated with respect to ammonium sulphate. The precipitate was collected by filtration and dialysed against cold distilled water. The dialysed preparation (retentate) was centrifuged and the supernatant discarded after assays showed that it contained only minimal activity as regards synthesis of sucrose.

The precipitate obtained from dialysis of the preparation from potatoes stored at 25° C. was suspended in 62 ml. of water. By analysis, each millilitre had 1·97 mgm. of protein nitrogen and was equivalent to 9·7 gm. of fresh potato tissue. Corresponding values for the enzyme preparation from potatoes stored at 2° C. were 65 ml. total volume, 1·73 mgm. protein nitrogen per ml., and each millilitre of enzyme represented 9·2 gm. of fresh potato tissue. Sucrose was determined by the method of Rorem *et al.*[3], in which the residual colour and reducing sugars are eliminated by the addition of sodium borohydride prior to development of colour with resorcinol. The formation of sucrose in the enzyme reaction mixture was also demonstrated by paper chromatography.

The rates of synthesis of sucrose compare favourably with those of crude preparations from other plant sources. No significantly great differences were observed between the enzymatic activity of the protein fraction from tubers stored at 2° C., in which sucrose accumulates, and that from tubers stored at 25° C., in which sucrose does not accumulate. Both preparations exhibit the same apparent *p*H optimum for synthesis of sucrose and both possess invertase activity. The *p*H optimum for sucrose synthesis (Table 1) is probably not the true *p*H optimum of the enzyme, since at *p*H 8·1 we found that the invertase activity drops off rather sharply from that found at *p*H 7·1, thus allowing more sucrose to accumulate at the higher *p*H. It will be noted that the presence of invertase in the preparation from potatoes stored in the cold resulted in a decrease in sucrose in the enzyme reaction mixture at *p*H 7·1 after prolonged incubation. The presence of invertase in these preparations also vitiated attempts to establish the equilibrium of the reaction.

Additional experiments showed that these potato preparations can synthesize sucrose or sucrose-phosphate when fructose-6-phosphate is substituted for fructose in the enzyme reaction mixture. The possibility of conversion of the fructose-6-phosphate to free fructose by a phosphatase, however, has not been completely eliminated.

In two sets of experiments, enzyme preparations from the White Rose variety, known to be a good sugar former, synthesized sucrose at a rate 3–4 times as great as similar preparations from Washington Russet. These preliminary experiments suggest that varieties which tend to accumulate large amounts of sugar contain more enzyme than those with smaller accumulation of sugar.

Table 1. MICROMOLES OF SUCROSE SYNTHESIZED BY ENZYME PREPARATIONS FROM WASHINGTON RUSSET VARIETY POTATO TUBERS

*p*H	Enzyme from tubers stored at 25° C.			Enzyme from tubers stored at 2° C.		
	Incubation time 1 hr.	2 hr.	4 hr.	Incubation time 1 hr.	2 hr.	4 hr.
7·1	0·156	0·193	0·222	0·085	0·096	0·047
7·5	—	0·234	—	—	0·272	—
7·8	—	—	—	—	0·425	—
8·1	—	0·376	—	—	0·471	—
8·4	—	0·290	—	—	0·460	—

The enzyme reaction mixtures containing 3 micromoles uridine diphosphoglucose, 8 micromoles fructose, 0·002 ml. of 0·1 *M* magnesium chloride, 0·04 ml. of 1 *M* *tris* buffer and 0·68 ml. of enzyme in a total volume of 0·8 ml. were incubated at 37° C.

These results appear to eliminate the possibility of induced uridine diphosphoglucose → fructose-transglycosylase formation in response to the altered environment as a factor in the accumulation of sucrose in potato tubers stored at low temperatures. The absence of radical changes induced by temperature in content of other enzymes involved in carbohydrate metabolism of potatoes, namely, phosphatase and amylase[6], and phosphorylase[7], suggests alternate mechanisms of enzyme control or control at less purely biochemical levels.

Optimal Protein Synthesis by Ascites Tumour Cells *in Vitro*

Warburg and Hiepler[1] have stated that ascites tumour cells show the highest metabolic rates when incubated in their own ascitic fluid. Littlefield and Keller[2] later showed that the incorporation of ^{14}C-amino-acids into mouse ascites cell proteins occurs at a rapid rate when the whole ascitic fluid is fortified with glucose and buffer salts and incubated in air. Incorporation is considerably greater than when buffer salts alone are used. More recently, Quastel, Bickis and Vas[3] reported that the sera of many different species of animals (rat, mouse, rabbit, guinea pig, ox) stimulate the incorporation of ^{14}C-glycine into the proteins of washed intact Ehrlich mouse ascites cells *in vitro*, in some cases by as much as fivefold. This stimulation of incorporation was also shown by the mouse ascitic fluid and by heated serum ultra-filtrates. The stimulation of incorporation of amino-acids into these cells by rat serum has now been investigated in greater detail and found to be due to the combined effects of glucose, glutamine, bicarbonate and amino-acids. These substances, used in the same concentrations as are found in the serum, can replace the serum fully (see Table 1).

Since the incorporations of different amino-acids were not stimulated to the same extent by rat serum under identical conditions (for example, glycine by 187 per cent, valine by 133 per cent, leucine and glutamic acid by less than 10 per cent), great care was taken to show that the stimulated incorporation occurred via the normal pathways for protein synthesis. Glycine incorporation was studied in detail in this respect. Techniques were employed

Table 1. INCORPORATION OF ^{14}C-GLYCINE INTO ASCITES CELL PROTEINS IN THE ABSENCE AND PRESENCE OF RAT SERUM AND SYNTHETIC SERUM MIXTURES

Additions	Specific activity of isolated protein (c.p.m./mgm.)	Activity relative to control
None (control)	41	1·00
0·28 m*M* glucose	69	1·68
0·66 m*M* glutamine	86	2·10
2·6 m*M* bicarbonate ($NaHCO_3$)	31	0·76
2·6 m*M* bicarbonate + 0·66 m*M* glutamine	96	2·34
0·28 m*M* glucose + 2·6 m*M* bicarbonate + 0·66 m*M* glutamine	104	2·54
0·28 m*M* glucose + 2·6 m*M* bicarbonate + 0·66 m*M* glutamine + amino-acids (0·5–45 μ*M*) (ref. 5)	144	3·51
Rat serum (0·3 ml.)	106	2·59
Rat serum + glucose + bicarbonate + glutamine (as above)	121	2·95
Rat serum + glucose + bicarbonate + glutamine + amino-acids (ref. 5) (as above)	124	3·02

Each incubation mixture contained 3·0 ml. (total volume) of a 3·3 per cent suspension of washed ascites cells (wet weight) in Krebs–Ringer phosphate buffer, *p*H 7·4. The initial concentrations of added glucose, bicarbonate and amino-acids are given and are equivalent to the addition of 0·3 ml. serum. The glutamine added was, in this case, equivalent to 3·0 ml. serum. The final concentration of glycine was 2·0 m*M* and contained 10^4 c.p.m. radioactivity.

in the isolation of 'protein' free of nucleic acid and lipids that are known to minimize the non-peptide bonding of amino-acids to protein[4]. The final products, when subjected to controlled acid hydrolysis, released radioactivity from the protein isolated from cells incubated in the absence or presence of heated serum ultra-filtrate at the same rate. When the samples were subjected to exhaustive acid hydrolysis (16 hr. in 6 *N* hydrochloric acid at 110° C.) and the products examined by two-dimensional chromatography and radioautography, carbon-14 activity was found only in the areas corresponding to the positions in which glycine and serine are found. About 20 per cent of the total label appeared as serine in both cases. Unlabelled serine depressed the labelling of the tumour-cell proteins by ^{14}C-glycine either in the absence or presence of the heated serum ultra-filtrate to the same extent, indicating that the glycine–serine interconversion was unaffected by the serum factors. When protein was isolated from the different cell fractions separated by ultracentrifugation in the usual manner[3], the debris—nuclei, mitochondrial, microsomal, supernatant, fractions soluble and insoluble at *p*H 5, though labelled to different extents, showed the same proportional increases when the cells were incubated in the presence of heated serum ultra-filtrates.

It would thus appear that 'stimulated incorporation' is not fundamentally different from ordinary incorporation. Some other explanation must be invoked to account for the different responses of different amino-acids to the serum-factors. One possibility is that there are different levels of the various ^{14}C-amino-acids in the 'pool' synthesized from the added amino-acid, which are afterwards utilized for incorporation. It may be also that considerably higher concentrations of some amino-acids are required to produce optimal levels of activated amino-acids for incorporation.

The responses of the ascites cells to the various components of the synthetic serum mixture are quite interesting. When a maximal stimulation of incorporation of ^{14}C-glycine by heated serum ultra-filtrate of 200–240 per cent was observed, 68 per cent of the effect could be obtained with glucose in the same amount as found in the rat serum, 110 per cent by glutamine alone, 134 per cent by glutamine plus bicarbonate, but only 154 per cent by combining all three. When an amino-acid mixture was also added, equivalent to the amounts found in human serum[5], a final stimulation of 200–250 could be obtained. Thus it appears that glutamine is a major factor in the serum and, since the mouse ascitic fluid is lacking in glucose, glutamine is probably a major factor in ascitic fluid for the stimulated incorporation of amino-acids. This effect of glutamine is well known[6], and probably results from the fact that washed ascites cells are deficient in glutamine due to the presence of a high intracellular glutaminase activity. There is little effect of glucose in combination with the other serum factors, yet it stimulates glycine incorporation by 68 per cent on its own, indicating that an 'energy source' is needed for optimal incorporation in these systems. It seems likely that glutamine can act indirectly through the actions of glutaminase and transaminase as an 'energy source' also. In every case the washed cells were incubated in Krebs–Ringer phosphate buffer, *p*H 7·4. The effect of adding bicarbonate alone (final concentration only 1–2 m*M*) was to depress the incorporation of glycine by 25 per cent. However, if added when glutamine is present, the stimulation due to incorporation of glycine is even greater than with glutamine alone. These effects are difficult to explain.

In summary, it can be said that the effects of serum, and probably of ascitic fluid also, in stimulating the synthesis of protein in ascites cells, are probably due to the presence of substances which lead to the production of increased levels of the activated amino-acids required for higher rates of protein synthesis. This can occur by supplementing the cells with deficient amino-acids and with 'energy sources' which can give rise to higher levels of adenosine triphosphate.

I thank Prof. J. H. Quastel for his suggestions and interest throughout this work, and the Rockefeller Foundation for a grant which made this work possible.

Effect of Heavy Water on Respiratory-chain Enzymes

DURING radiobiological work on bacteria it was found by one of us (H. L.) that the effect of ionizing radiation (X-rays) is greatly potentiated if the bacteria are irradiated in a medium in which water is replaced by heavy water[1]. Thus, for example, with *Escherichia coli B* and *Pseudomonas* 6009 the dose-reduction factor was approximately 2, that is, the X-ray dose required to produce a given reduction in the number of colony-forming bacteria on irradiation in deuterium oxide was one half that in water. This effect, however, occurred only if the bacteria were irradiated in presence of oxygen, but not, or only insignificantly, after irradiation under anaerobic conditions.

Heavy water has for some time been known to affect a variety of chemical reactions and biological processes[2], the rates of which, as a rule, are slowed down.

In the present experiments the respiratory-rate of the bacteria used was decreased by approximately 45 per cent and that of baker's yeast by 75 per cent in 95–98 per cent deuterium oxide, as compared with water medium, the inhibition becoming apparent immediately at the beginning of the experiment. The rate of anaerobic fermentation of *E. coli*, on the other hand, was not affected by deuterium oxide for the first 2 hr. (An inhibition developed after 2 hr.)

Similarly the rate of aerobic succinate oxidation in the Keilin and Hartree heart-muscle preparation was increasingly inhibited with increasing concentrations of deuterium oxide, maximal inhibition being between 45 and 50 per cent in 99 per cent deuterium oxide, while the rate of anaerobic oxidation of succinate with methylene blue as hydrogen acceptor was not affected.

In order to gain further insight into the mechanism responsible for metabolic effects of deuterium oxide as manifested, for example, in inhibition of respiration in intact cells and of oxidations in isolated enzyme systems, further experiments have been undertaken.

Table 1. EFFECT OF DEUTERIUM OXIDE ON RESPIRATORY-CHAIN ENZYMES IN HEART-MUSCLE PREPARATION

Enzyme activity	Inhibition (per cent) by 95–99 per cent deuterium oxide
Succinate-methylene blue	5
Succinate-ferricyanide*	26
Succinate-cytochrome *c*	37
Succinate-O_2	35
DPNH-methylene blue	3
DPNH-cytochrome *c*	34
DPNH-O_2	34
Cytochrome *c*-O_2	52

* In the presence of antimycin.
DPNH, reduced diphosphopyridine nucleotide.

The results given in Table 1 show that replacing the water in the medium by 90–99 per cent deuterium oxide inhibited the oxidation of succinate by oxygen, ferricytochrome *c* or ferricyanide, and the oxidation of reduced diphosphopyridine nucleotide by oxygen or ferricytochrome *c*, in the presence of heart-muscle preparation. The cytochrome *c* oxidase reaction was also inhibited (cf. ref. 3). On the other hand, oxidation of succinate or of reduced diphosphopyridine nucleotide by methylene blue with heart-muscle preparation was not appreciably inhibited.

Table 2. EFFECT OF DEUTERIUM OXIDE ON RATE OF OXIDATION OF SUCCINATE BY RAT-LIVER MITOCHONDRIA AND ON P : O RATIO (0·06 *M* SUCCINATE)

Exp.	Activity of control		Inhibition (per cent) by deuterium oxide	
	Q_{O_2}*	P : O	In absence of dinitrophenol	In presence of 3×10^{-4} *M* dinitrophenol
1	90	1·71	7	0
2	114	1·58	21	0
3	142	—	21	—
4	146	—	29	16
5	163	1·73	29	6
6	262	—	58	26

* µl. oxygen/mgm. protein/hr.

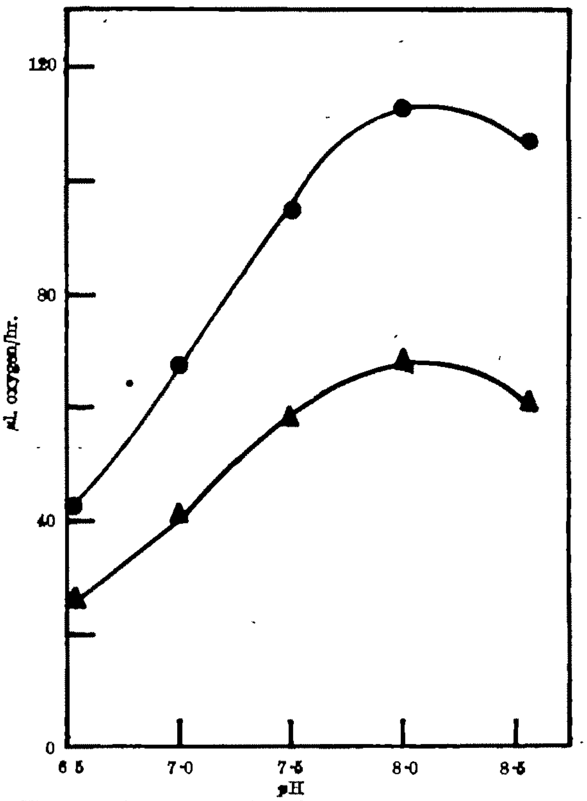

Fig. 1. Oxidation of succinate by heart-muscle preparation in (●) H_2O and (▲) D_2O medium as a function of *p*H

The inhibition of succinate oxidation catalysed by rat-liver mitochondria was variable, being greater with preparations having a higher activity (Table 2). The degree of inhibition was considerably decreased by the addition of 3×10^{-4} *M* dinitrophenol, which inhibited the rate of oxidation only slightly (7–34 per cent). Deuterium oxide decreased the P : O ratios only slightly, both in the presence and the absence of dinitrophenol.

The experiment described in Fig. 1 shows that replacement of water by deuterium oxide did not alter the *p*H optimum of the succinic oxidase activity of heart-muscle preparation and that the degree of inhibition was practically independent of *p*H (or *p*D) between 6·5 and 8·6. Thus the inhibition is not due to a possible difference in the degree of ionization of water or deuterium oxide or of the buffer in water and deuterium oxide.

The enzyme-catalysed reductions of methylene blue by reduced diphosphopyridine nucleotide and by succinate, which were not inhibited by deuterium oxide, represent probably a simple transfer of hydrogen atoms from substrate to methylene blue, catalysed by the respective dehydrogenases and intermediate carriers. These reactions are not accompanied by phosphorylation in mitochondrial preparations. However, those reactions which involve larger segments of the respiratory chain, and which are associated with phosphorylation in mitochondrial preparations are inhibited by deuterium oxide in the non-phosphorylating heart-muscle preparations.

The inhibitions given in Tables 1 and 2 were determined immediately after adding the enzyme preparations to the reaction mixture. They cannot, therefore, be due to a possibly decreased reaction-rate with deuterium-labelled substrate, formed by exchange reactions, since these are relatively slow[4] and could not become manifest at once.

We should like to suggest as explanation of these results that a protonolysis is a rate-limiting step of the respiratory chain in non-phosphorylating preparations, and that replacement of H+ by the heavier D+ slows down these reactions[2,3]. It seems particularly significant that the succinic oxidase of phosphorylating preparations is considerably less inhibited in the presence of dinitrophenol, which is believed to increase the rate of hydrolytic reactions[5].

As yet, however, no basis has been found for explaining the potentiation of radiation effects in deuterium oxide.

Influence of Different Types of Malnutrition on the ^{14}C-Lysine Metabolism in Young Rats

IN the usual laboratory animals the typical corollaries of chronic shortage of proteins, fats, and carbohydrates have been thoroughly studied. Very little is known, however, of the changes in the intermediary metabolism. Since we were interested from a pædiatric point of view in the problems of malnutrition, we have investigated weanling Wistar rats (body-weight 35 ± 5 gm.). Five groups of ten animals each received for one week or more a synthetic diet (adapted from György) of the composition shown in Table 1.

Table 1

	Group I	Group II	Group III	Group IV	Group V
Carbohydrates	69		5	85·4	74·3
Proteins	20	50	68	2	21·4
Fats	6·7	per cent	22·7	8·3	0
Salts, vitamins and 'Nestargel R'	4·3	of Group I	4·3	4·3	4·3

On the seventh, eighth, and ninth days two animals of each group were placed in a metabolism cage. After adaptation to the new surroundings, each animal was injected intraperitoneally with 10μc.^{14}C-lysine. Six hours later the animals were killed and the proteins of the different organs were isolated and their specific activity was determined in a methane flow counter as described in detail elsewhere[1].

A diminution of the calorie intake of 50 per cent did not influence the rate of incorporation of the labelled lysine into the proteins of any organ examined. This finding is in accord with the studies of Allison[2], and Cox *et al.*[3], which were based on results of experiments done with classical methods.

The results from our Groups III and V showed that there is no difference in the protein-sparing action of fat and carbohydrate, so far as it is possible to draw this conclusion from experiments with a single labelled amino-acid. But this finding agrees well with results obtained by the usual metabolic methods[4]. Of course only monosaccharides show a specific depression of the amino-acid-level in blood in experiments of short duration[5]. Fructose does not bring about higher retention of nitrogen than glucose[6] as has been claimed by others[7]. The specific activities of the organ proteins were in the same range as those of the group on a mixed diet (Group I). This is remarkable since the rats of Group III received a diet very rich in protein.

On the other hand, the animals on the diet almost free from protein, as is seen from Table 2, incorporated tagged lysine in several organs at a significantly higher rate than those of all the other groups. Since the carbon-14 dioxide production from lysine was only about 50 per cent of the other animals, one can postulate that the oxidative deamination of the amino-acid decreased in the protein-free animals in favour of protein synthesis.

Table 2. SPECIFIC ACTIVITY OF THE PROTEINS OF ORGANS OF PROTEIN-STARVED RATS COMPARED WITH NORMALLY FED ANIMALS (TAKEN AS 100 PER CENT)

Organs	6th day	8th day	9th day
Liver	137	222	412
Kidney	131	184	279
Heart	128	186	300
Brain	107	245	726
Intestines	109	116	280
Muscle	65	85	73
Skin	90	85	83
Plasma proteins	221	212	251
Erythrocyte stroma	26	10	23
Hæmoglobin	81	8	22

Recently, Russian authors[8], in work on dogs, and also Garrow[9] and Waterlow[10], made similar observations; their experiments were carried out with ^{35}S-methionine.

Since we believe that protein synthesis is possible only when all necessary amino-acids are available simultaneously, one may postulate that, in protein starvation, the size of the pool of amino-acids is increased in those organs in which a higher rate of incorporation of ^{14}C-lysine is detectable. This can of course occur through a decreased breakdown, as we found to be the case in our animals. Lysine as such is not able itself to accelerate protein synthesis.

The radioactivity on the deproteinized blood plasma of the protein-starved rats was lowest in all the groups. In the liver, nevertheless, we had a relatively high count. Kreuger and Wiss have found with the microbiological amino-acid method a high content of free amino-acid in this organ in starved animals. Since the carcass proteins apparently do not partake in the increase in the rate of incorporation of lysine, it is evident that re-direction of the protein metabolism takes place in favour of vital enzymes and structures in the intestinal organs.

This interpretation is supported by the work of Solomon and Tarver[11] and of Waterlow[10], who have also found a shift in the rate of incorporation between the peripheral organs and the intestines. The changes in protein metabolism due to a protein shortage in the diet of longer duration proceed apparently in two phases: first, labile proteins which have a very short half-life are mobilized from the liver, etc.; later the 'less vital' structure proteins of the carcass are broken down and erythropoiesis is slowed down, whereas in the liver, kidney, intestines, and surprisingly in the brain too, neosynthesis is very active. The effect of protein starvation on protein synthesis is somewhat similar to that of glucocorticoids, which according to Hess and Shaffran increase the specific activity of liver proteins and decrease the rate of incorporation into the connective tissue and muscles.

PHYSIOLOGY

Dextran and Insulin in Rats

WHILE testing the effects of insulin on the circulatory reaction of laboratory rats to dextran, we found that many animals died after combined doses of the two agents which were not lethal when administered separately. The validity of this observation was put to experimental test. Male Sprague-Dawley rats weighing at least 150 gm. and fasted 24 hr. were subcutaneously injected with zinc insulin ('Iletin') at two dose-levels, 7·5 or 10 u./kgm. body-weight. An hour later dextran was administered by vein in a total volume of 10 ml./kgm. 0·85 per cent sodium chloride containing either 60 or 600 mgm. dextran ('Expandex'). Control animals received saline without dextran. Fatalities due to these amounts of dextran have not occurred in our work. The results of eight experiments are summarized in Table 1, which shows the incidence of survival after 24 hr. Animals that died exhibited convulsions usually within 3 hr. of insulin administration. Few signs of the dextran reaction characteristic of this species were noticed.

Table 1. EFFECT OF INTRAVENOUS ADMINISTRATION OF DEXTRAN ON SURVIVAL OF FASTED RATS AFTER INSULIN

No. survived/total number

Insulin u./kgm.	Dextran (mgm./kgm.) 0	60	600
7·5	16/20	5/20	13/20
10	13/26	4/26	20/26

The smaller dextran dose caused more stress than the larger at both insulin-levels. Comparison between the insulin doses (2 × 3 table) showed the results were not significantly different, so they were combined. The data were tested in 2 × 2 tables using χ-square with Yates's correction. Although not independent, these tests indicated that the decreased incidence of survival after 60 mgm./kgm. dextran was highly significant when compared with controls or with the number surviving after 600 mgm./kgm. The incidence of survival in the latter groups did not differ significantly from each other.

Aggravation of the dextran reaction in rats measured by oedema and blueing has been reported to follow insulin pretreatment[1,2]. We have found no previous mention, however, of the effect of dextran on this species' reaction to insulin, possibly because the observations were not continued long enough, or the insulin dose was too small. The occurrence of fatal convulsions after insulin doses which without dextran are subconvulsive may be due to indirect effects of dextran. One of these is severe and prolonged vasodepression[3], which would accentuate the already low glucose-level in the central nervous system. This situation could also prevail if vasoconstriction comparable to that seen in the mesoappendix and skin of the rat after intravenous administration of dextran[4] occurs likewise in the small vessels of the brain. Possible direct effects of dextran on resistance to insulin include changes in cellular permeability and blood sugar. Insulin in amounts too small to change the level of blood-sugar significantly has been reported to enhance oedema formation after subcutaneously administered dextran[5]. Our investigations of the manner in which dextran administered by vein affects insulin hypoglycaemia and the incidence of convulsions are continuing.

Summative Action of Acetylcholine with Physiological Stimulus on the Generator Potential in the Lateral Eye of the Horseshoe Crab

THE action of acetylcholine on the electrical activities of various receptors has been studied by many authors[1]. Most of the investigations of its action were carried out on the responses of receptors in terms of impulses they discharge. In this communication the effect of acetylcholine on the retinal slow potential, which is regarded as a generator potential[2], was studied by means of intracellular micro-electrodes. The electrical activities arising within single ommatidia of the excised lateral eye of the horseshoe crab (*Tachypleus tridentatus*), which was immersed in the physiological saline solution[3], were led to a cathode follower through a micro-electrode filled with 3 *M* potassium chloride.

Having obtained the responses by illumination of a given intensity, duration and interval as controls (*a* in Fig. 1), the solution made by dissolving acetylcholine chloride in physiological saline solution was added by a micropipette to the external solution of a known volume. Then the responses by the same stimuli were successively recorded. The concentration of acetylcholine was calculated afterwards.

As seen in Fig. 1*b*, a remarkable increase in the amplitude of both the initial maximal and the successive less but steady depolarization was induced by the addition of acetylcholine. Moreover, prolongation of the falling phases of the initial maximal depolarization and the phase of repolarization following cut-off of the stimulus also occurred.

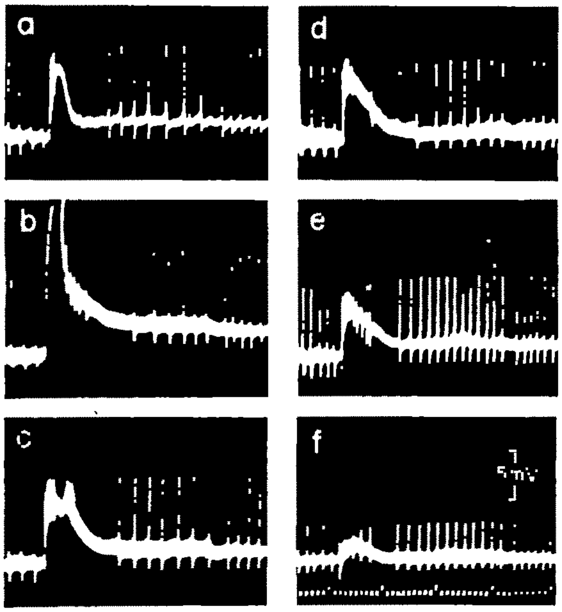

Fig. 1. Summative action of acetylcholine with illumination on the retinal slow potential. *a*, Control; *b–f*, records taken successively at every two minutes following addition of acetylcholine (5×10^{-4} mole). All records were obtained after 60 sec. in darkness. Pips indicate on- and off-signs. Time, 1 + 0·1 sec.

These effects could be obtained without any significant change in the resting potentials soon after the addition of acetylcholine. Sometimes two humps were formed as a result of the appearance of another hump at the falling phase of the initial maximal depolarization (Fig. 1c). This effect of acetylcholine on the generator potential of the eye of the horseshoe crab suggests that its summative action with natural stimuli reported in some other receptors may, at least, be partially due to its effect on their generator potentials.

The summative effect of acetylcholine was always followed by its depolarizing action (Fig. 1*d–f*), and the activity of the cell did not return to normal by application of normal saline solution.

Strychnine and 2,4-dinitrophenol elicited a reversible increase and a prolongation of the retinal slow potential of the horseshoe crab. But the effect of acetylcholine was more difficult to find, for an unknown reason, than that of the former two chemicals, though it was more remarkable at a lower concentration if it did appear. In most cases only the depolarizing action was exhibited following the addition of acetylcholine. The dosage differed from one preparation to another, as reported in other receptors[1], and the minimum effective concentration was 5×10^{-4} moles in our experiments.

In addition, the mode of action of acetylcholine is somewhat different from that of TEA. The latter compound belongs to the quaternary ammonium compounds as does acetylcholine, but it exhibited not only the summative action with natural stimulus but also induced spontaneous pulse-shaped prolonged potentials in the presence of sodium ions, as is reported in the giant axon of the squid[5].

Fuortes[4] suggests that the photoreceptor in the *Limulus* eye liberates a chemical product during illumination. But there remain difficulties in assuming that acetylcholine is the product in question according to our observations, since its summative action with natural stimulus could appear separately from its depolarizing action, and seemed not to be influenced by atropine or anticholinesterase in the experiments performed so far.

In any event, acetylcholine seems to have two actions on the sensory cells in ommatidia of the horseshoe crab; one is the summative action with physiological stimulus which may be explained as the sensitization of the chemical product or acceleration of its liberation during illumination, and the other is its depolarizing action on the cell membrane concerned.

*p*H Changes during Muscle Twitch and Tetanus

Dubuisson[1-3] has shown that *p*H variations during muscle activity can be recorded at the muscle surface with a glass electrode, using an electrometer and a sensitive galvanometer. Displaying the d.c. amplified electromotive force changes of the glass electrode, on the screen of a cathode-ray tube, reduces the recording delay to a few msec., and makes it possible[4] to estimate the time constant of the glass electrode (McInnes type), transmitting a *p*H step, to be about 30 msec.

The recordings during muscle activity are made with a small electrode (20 mm. long, diam. of flat sensitive membrane, 4 mm.). It is attached laterally to the hanging muscle, and a counter-weight arrangement makes it follow the muscle movements.

Fig. 1 shows the *p*H changes during single isometric twitches of a tortoise muscle at 22° C. The curves have been corrected[4] to take into account the diffusion time of carbon dioxide through the film of liquid and inert material (6μ) between the electrode and the muscle surface. The zero of the time-scale coincides with the beginning of the action potential, which is recorded in an attenuated form by the electrode. This introduces some uncertainty at the beginning of

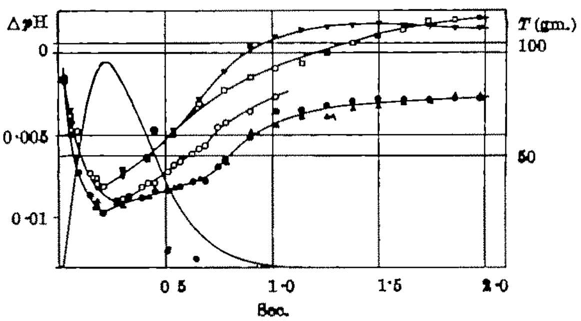

Fig. 1. *p*H variation during four successive isometric twitches (first twitch below, acidification downwards). Tortoise iliofibularis, *p*H 7·2, 22° C. Right ordinate: tension in gm.

the *p*H curves; but careful examination of hundreds of records leads to the conclusion that the initial acidification (phase *b* of Dubuisson) does start during the action potential. The much slower alkaline shift (phase *c* of Dubuisson linked to phosphagen breakdown) is often absent during the first twitches sustained by a muscle after a long rest and builds up gradually to a maximum during following twitches. The fast acid phase is always present. Its Q_{10} is high, ~ 3·2 for tortoise muscle and lies between 3·2 and 3·8 for frog muscles.

If this initial change in *p*H is assumed to be due to the hydrolysis of ~ P bonds, from adenosine triphosphate or any other carrier provided it liberates the same amount of H⁺ at a given *p*H according to its electrotitration curve, one can calculate the amount of split ~ P if one further knows the cellular carbon dioxide/bicarbonate ratio, the *pK'* of carbonic acid, and the retention factor which accounts for other buffer systems. Taking a minimum of 1·10 for this factor, values between 0·04 μmole/gm. and 0·1 μmole/gm. for tortoise muscles and 0·06 μmole/gm. and 0·18 μmole/gm. for frog muscles are found for the amount of ~ P split per twitch. The best results correspond to 60–70 per cent of the minimum expected change (0·25 μmole/gm. for frog muscle) estimated from myothermic data[5]. The discrepancy, if not real, might be due to an under-estimation of the retention factor which is calculated from equilibrium measurements.

The *p*H variations observed during a single twitch are summed during tetanus, giving rise to *p*H curves similar to that described by Dubuisson. Assuming that a diphasic *p*H change is produced at each stimulus, in the range of frequency investigated, the experimental records can be reconstructed by simple algebraic summation, as shown in Figs. 2 and 3. It is seen that in these particular cases the absorption of H⁺ overcompensates the H⁺ liberation after a few stimuli, and that a linear steady state is established, which abruptly ends when stimulation stops. The final alkaline burst is in fact made visible by the cessation of H⁺ production. The rate of H⁺ liberation, corresponding to the accumulation of the fast acid changes described for single twitches, can be calculated from the *p*H recordings, and one obtains the curves shown in the upper sections of Figs. 2 and 3, giving the carbon dioxide production in μmole per c.c. of extracellular liquid.

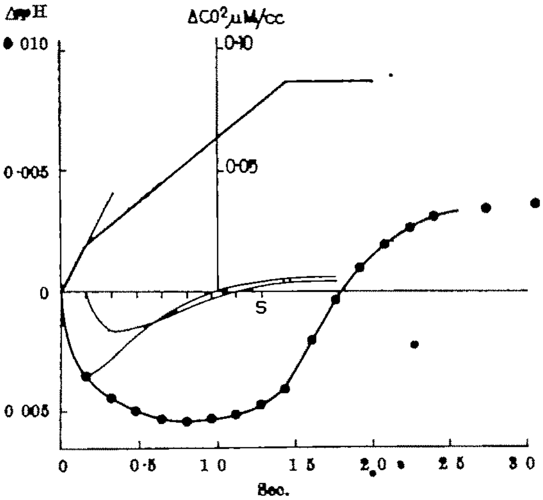

Fig. 2. *p*H change (full line downwards) during short tetanus. Tortoise ileofibularis, *p*H 7·0, 22° C. Stimulation ends at *S*. The circles are calculated by summing diphasic *p*H changes produced at each stimulus. Above: carbon dioxide production (μmole/c.c.) corresponding to the sum of the fast acid phases

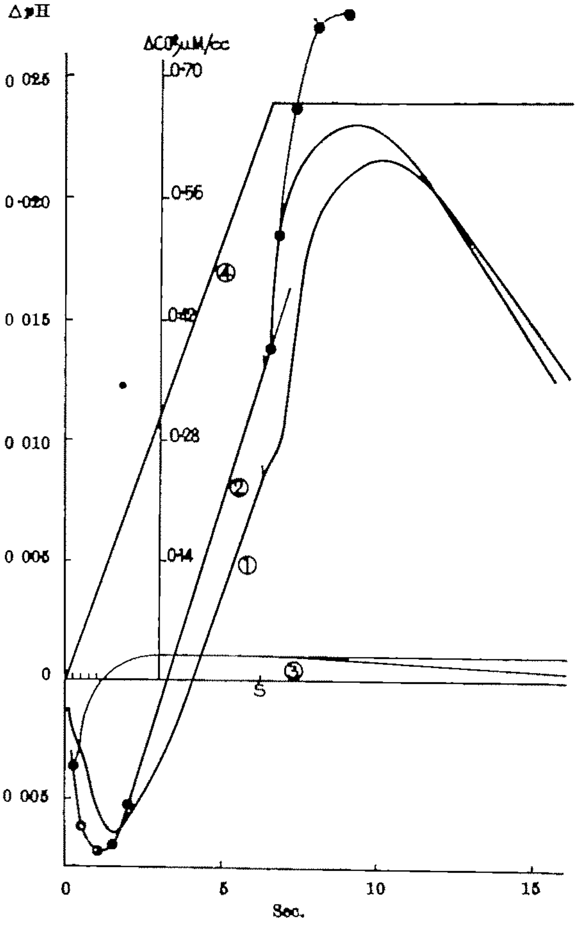

Fig. 3. (1) Recorded *p*H change (tetanus, tortoise ileofibularis, *p*H 6·8, 22° C.). (2) *p*H curve corrected for the lag due to diffusion. The circles result from the summation of 26 diphasic *p*H variations corresponding to a single twitch (curve (3)). Introducing a slow component in (3) leads to curve (2). Curve (4) represents the sum of successive fast acid phases, in μmole carbon dioxide/c.c.

If one admits that phase *b* of Dubuisson corresponds to an exothermic reaction (~ P splitting) and phase *c* to an isothermic process (~ P transfer), there is a good qualitative agreement between the H⁺ production and the heat production during tetanus[7]. Quantitatively, the calculated rates of liberation of energy are, however, too small to account for the whole of the maintenance heat in the same proportion as observed for single twitches.

The intensity of phase *b* is linked to previous work done by the muscle and depends on the initial length. Qualitative indications exist such that the H⁺ liberation during isotonic contractions depends on the amount of shortening.

Metabolism of Oxygen-15

OXYGEN-15 has been prepared by deuteron bombardment of nitrogen molecules in the Medical Research Council cyclotron at Hammersmith Hospital. Gases labelled with this isotope, which has a half-life of only 2 min., can be inhaled into the lungs and detected by external scintillation counters. The initial counting-rate in a given region of the lung is proportional to the regional ventilation[1], and the rate of removal from the region during breath-holding is a measure of the regional blood-flow[2].

During some of these experiments the radioactivity in the blood was measured at intervals after the breath was taken. Blood samples were taken from a forearm vein in four subjects between 15 sec. and 4 min. after the beginning of the breath of air, the oxygen of which was labelled with oxygen-15. The samples were heparinized and centrifuged for 2 min. to separate the cells from the plasma. The radioactivity of 2-ml. samples of red cells and plasma was measured in a sensitive 'well' type crystal scintillation counter. In a further study, 20 ml. fresh blood at 37° C. was labelled with oxygen-15 by bubbling a stream of the isotope in air through it. A sample was taken from the blood immediately after labelling and after 5-min. incubation at 37° C. and the radioactivity in both red cells and plasma was measured.

A typical example of the changes in the radioactivity in the plasma and red cells for 4 min. following the breath of oxygen-15 (corrected for radioactive decay to a common zero time) is shown in Table 1. The radioactivity in the plasma increased rapidly and the red cell activity fell during the 4 min. of observation. In consequence the proportion of the radioactivity in the plasma increased from 10·6 per cent after 30 sec. to 53 per cent after 240 sec. The results in all four normal subjects followed a similar pattern.

When blood was labelled *in vitro* only 1 per cent of the radioactivity appeared in the plasma, and this proportion did not alter significantly after 5 min. incubation. This is the proportion which would be expected from the known partition of molecular oxygen between red cells and plasma.

The rising plasma radioactivity found *in vivo* must represent the return to the plasma of oxygen-15 which has been metabolized in the body cells. The results show in a striking way how rapidly this takes place. An appreciable fraction of the inhaled molecules of oxygen-15 is transported by the blood to the tissues, diffuses into the tissue cells, is metabolized and then diffuses back into the blood within 30 sec. of the beginning of the breath.

An attempt was made to fractionate the radioactivity in the plasma into carbon dioxide and water by acidifying and shaking under vacuum, but none of the radioactivity could be removed. This is because oxygen-15, which is metabolized to carbon dioxide, becomes freely exchangeable with the oxygen in water when bicarbonate is formed in the blood, and therefore cannot be separated.

Table 1. RED CELL AND PLASMA RADIOACTIVITY CORRECTED FOR RADIOACTIVE DECAY TO A COMMON ZERO TIME

Time after breath (sec.)	Red cell radioactivity (counts/min./ml.)	Plasma radioactivity (counts/min./ml.)	Ratio plasma/red cell activity (per cent)
30	102,000	10,800	10·6
60	104,000	12,500	12
120	78,000	21,600	28
240	55,000	29,000	53

The Membrane Potential of the Anterior Byssus Retractor Muscle of *Mytilus edulis*

As yet no reports of intracellular recording from the anterior byssus retractor muscle appear to have been made. The membrane potential can be measured with conventional glass micro-pipettes filled with 2·5 *M* potassium chloride, but satisfactory recordings have only been obtained with electrodes possessing tips of about 0·5μ or less in external diameter. Very few such electrodes are free from large tip potentials; but some satisfactory recordings have been obtained from the muscle *in situ*, using selected electrodes.

The animal was opened and the muscles of one side cut through leaving the byssus attached to one anterior byssus retractor muscle in one half of the shell. The shell was mounted horizontally and filled with sea water, and tissue covering the anterior byssus retractor muscle was carefully cleaned away, leaving the muscle exposed. The recording electrode was connected direct to the grid of a cathode follower (6*BS*7 selected for low grid current) through a silver–silver chloride/sea water–agar bridge. The sea water in the shell was earthed via a similar bridge. Calibration voltages were applied across a 50-ohm resistor between earth and the shell. Signals from the muscle were taken through a d.c. amplifier and displayed on a pen-writing oscillograph. Membrane potentials recorded fell within the range 30–50 mV., but potentials from the same muscle were within a range of 7 mV. or less. The mean value was 39 ± 2 mV. (*S.E.* of 14 observations).

Effect of Size of Pupil on Visual Acuity

DENTON[1] has suggested that a possible function of the pupil light reflex might be to provide apertures optimum for visual acuity at different light intensities. At low levels of luminance visual acuity is probably limited by the rate at which light quanta activate the retinal receptors[2], and thus a large pupil admitting the maximum amount of light would appear to be advantageous. As the luminance is increased into the photopic range, loss of image contrast due to optical aberrations, diffraction, and stray light also tend to limit visual acuity, although the fineness of the retinal cone mosaic may[3] ultimately become the limiting factor. The decrease in pupil size which normally accompanies increase of illumination should reduce to some extent the deleterious effects on visual acuity of the optical aberrations. However, it has never been shown that the actual response of the pupil reflex to a given steady luminance does in fact result in an aperture giving maximum spatial resolution at this luminance. It was therefore decided to determine experimentally whether an optimum aperture existed at each luminance-level, by measuring the relations between pupil size, luminance, and visual acuity over a wide range.

In these experiments the pupil was dilated by instilling 2 per cent homatropine hydrobromide into the conjunctival sac. The instrument used to measure visual acuity at different luminances consisted of a tube 33 cm. long and 3 cm. in diameter. At one end of the tube was placed a disk, carrying apertures 1–8 mm. in diameter at 0·5 mm. intervals, which could be placed close to the eye so as to act as a variable entrance pupil. Close to this artificial pupil was placed an adjustable neutral wedge filter. At the other end of the tube was situated a circular ground-glass screen, subtending an angle of 5°, which was illuminated by an opal tungsten lamp of colour temperature 2,800° A. Luminances were measured with an *S.E.I.* photometer (Ilford) that was checked periodically against a calibrated standard lamp.

To measure visual acuity, a test pattern was placed in a holder in front of the ground-glass screen. The test pattern finally adopted contained a series of grating patterns with lines of different separation, each grating consisting of three opaque bars on a translucent background, the separation of the bars being equal to their width. All the different patterns are visible at the same time, avoiding the necessity of changing the pattern between each reading. The subject was instructed to look at a given pattern and then to increase the luminance by moving the wedge until the separate lines of pattern were just discriminated. Only vertical lines were used so as to eliminate the effects of uncorrected astigmatism. Lenses could be placed close to the eye to correct for refractive errors and also to allow for the proximity of the test pattern. The four subjects used were experienced at making visual observations of the type occurring in these experiments.

The results from a single typical run are shown in Fig. 1. Each curve represents the lowest luminance at which a given test pattern can be discriminated at various pupil sizes. For example, the largest test object used subtended an angle of 5·7 min., and it is clear that with increase of pupil diameter the test object is perceived at successively lower luminance-levels up to the maximum pupil size of 8 mm. However, for smaller test objects the minimum luminance occurs at pupil diameters less than 8 mm., and with reduction of test object size the optimum pupil diameter decreases progressively from 8 to 2 mm. All the curves show a rapid increase in threshold luminance as the pupil diameter is decreased below 2 mm., presumably due to the dominance of diffraction effects[3,4].

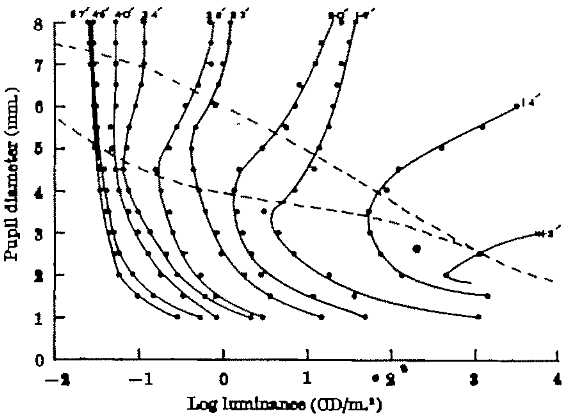

Fig. 1. Results of single run on subject A. H. G. Curves for different acuity patterns represent the lowest luminance at which the pattern is visible at various pupil sizes. Broken lines indicate natural pupil size as determined by Reeves (upper line) and Crawford (lower line)

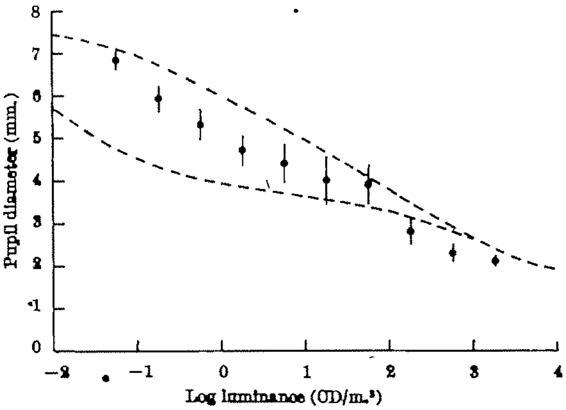

Fig. 2. Mean values of optimum pupil size from maxima of acuity curves such as in Fig. 1. Points represent means from 13 runs on 4 subjects, and extent of vertical lines indicates standard error of mean. Broken lines indicate natural pupil size as in Fig. 1

The smaller test patterns show a well-defined optimum pupil size, the threshold luminance increasing rapidly for pupil sizes on either side of this optimum value. For large test objects, the optimum pupil size is less well defined, and for even larger objects, involving parafoveal vision, the threshold will still be decreasing when the maximum available pupil diameter of 8 mm. is reached.

The results in Fig. 1 are from subject A. H. G. (age 23 years). Three other subjects, F. W. C., J. G. R., and R. R. (ages 35, 22, 26 years respectively) gave similar curves. To determine whether the type of test target influenced the results, F. W. C. performed two runs on each of three different targets (Landolt C, multi-bar grating, and three-bar grating). The optimum pupil size was found to be independent of the type of test target, but as the three-bar grating proved to be most convenient, this was used for the remaining subjects. Three runs were performed on A. H. G. and two each on J. G. R. and R. R. The mean optimum pupil sizes for these thirteen trials on four subjects are shown in Fig. 2, the means being taken over successive units of 0·5 log luminance. The vertical lines indicate the standard error of each mean.

Reeves[5] and Crawford[6] have published measurements giving the natural pupil size (with binocular viewing) at different luminance-levels, the subjects being fully adapted to each level. Their mean results, for seven and ten subjects respectively, are shown by the broken lines in both Figs. 1 and 2. The difference in their mean value is more marked at low luminance-levels, and may well be due to the dependence of maximum pupil size on age[7]. In Fig. 2 the mean optimum pupil sizes determined as above can be compared with the mean natural pupil sizes as measured by Reeves and Crawford. Although only a small number of subjects was used, the correspondence is good. We therefore conclude that the human pupil light reflex subserves the useful role of adjusting the aperture of the eye so as to optimize visual acuity over a wide range of luminance.

With the evidence at present available, it is difficult to decide whether the performance characteristics of the light reflex have been determined genetically by natural selection or by modification resulting from experience in each individual. Direct correlation between optimum pupil size and attained pupil size at different luminance-levels in a series of individuals might indicate the origin of the performance characteristics of the pupil.

Some of the apparatus used in this work was supplied by grants from the Royal Society and the W. H. Ross Foundation.

RADIOBIOLOGY

Labilization of Deoxyribonucleic Acid in Thymus Nucleoprotein after Whole-body Irradiation

The effect of total-body irradiation on the nucleoprotein in the sensitive organs can be demonstrated by a decrease of the viscosity[1]. Besides this, it has been shown that there is also a "labilisation of deoxyribonucleoprotein-moiety"[2] after a total-body irradiation and probably "the chromosome breaks may originate mainly in the junction of DNA particles with histone"[3]. To explain the effect of irradiation on nucleoproteins, it is probably necessary to study in more detail the binding between the deoxyribonucleic acid and the protein before and after irradiation.

The work of Kirby[4] provides a basis for such studies. According to this author, deoxyribonucleic acid can be extracted from tissues with 90 per cent phenol only in the presence of certain anions. These anions apparently break the bivalent metal linkages between the acid and protein. A small yield of deoxyribonucleic acid can be obtained with water; at increasing salt concentrations there is an increasing yield of deoxyribonucleic acid until all the acid becomes soluble. This phenomenon has been used in the present work as a measure of the firmness of binding the deoxyribonucleic acid to its protein.

Rats of an inbred strain of our own were irradiated with 200-kV. X-rays (10 m.amp., 210 r./min.). Desired tissues were taken immediately after decapitation, cooled on solid carbon dioxide, weighed, and homogenized with nine volumes of ice-cold water. To 2-ml. aliquots of the homogenate were added 2 ml. of trichloracetate of different concentrations (0–10 per cent). After 30 sec., 4 ml. of 90 per cent phenol were added and the mixture was shaken for 20 min. at room temperature, then centrifuged (15 min. at 0° C., at 15,000*g*). The clear supernatant was assayed for deoxyribonucleic acid by Dische's method[5]. A maximum yield of deoxyribonucleic acid was obtained with 2 per cent trichloracetic acid, which is noted as 'total deoxyribonucleic acid', as the extraction of the thymus with 5 per cent trichloracetic acid according to Schneider's method[6] gives no considerably higher acid values.

Table 1. AMOUNT OF DEOXYRIBONUCLEIC ACID EXTRACTABLE FROM THE THYMUS OF THE RAT WITH PHENOL-TRICHLORACETATE (MGM. ACID PER GM. TISSUE)

Trichloracetic acid final concentration	Normal thymus	Thymus 6 hr. after 800 r.	Thymus 12 hr. after 800 r.
(per cent)			
0	0·87 ± 0·202	2·33 ± 0·23	3·54 ± 0·83
0·5	0·89 ± 0·118	7·28 ± 0·69	8·85 ± 1·10
1·0	2·28 ± 0·28	18·42 ± 2·13	18·5 ± 0·1
1·5	27·1 ± 2·32	34·5 ± 0·85	28·4 ± 1·6
2·0	27·76 ± 0·78	32·65 ± 2·26	37·1 ± 2·5
5·0	20·8 ± 2·58	31·75 ± 1·5	42·2 ± 0·2

Each value represents 12–21 animals with standard deviation.

Table 1 presents the yields of deoxyribonucleic acid from normal thymus. After a whole-body irradiation, considerably more acid can be extracted from the thymus, especially with the more dilute trichloracetic acid solutions.

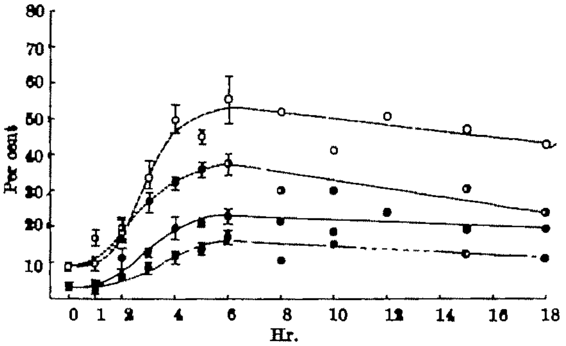

Fig. 1. Yield of deoxyribonucleic acid in extractions of thymus with phenol–trichloracetate after whole-body irradiation (yield in percentage of total acid). Time after irradiation. (Points with standard deviation represent 12–21 animals; single points represent three animals; trichloracetic acid final concentration in the supernatant). ---○---, 1·0 per cent trichloracetic acid, 800 r.; ---◑---, 1·0 per cent trichloracetic acid, 200 r.; ——●——, 0·5 per cent trichloracetic acid, 800 r.; -.-.-◐-.-.-, 0·5 per cent trichloracetic acid, 200 r.

The time relationships are more fully illustrated in Fig. 1. Since the total deoxyribonucleic acid per gm. of tissue changes after irradiation, the yield of deoxyribonucleic acid extracted with 0·5 and 1·0 per cent trichloracetic acid is calculated as percentage of the total deoxyribonucleic acid. After a lag period of about 1 hr., the yield increases for about 6 hr., after which it remains constant or decreases slightly.

The increase in yield of deoxyribonucleic acid extractable with dilute trichloracetic acid is dependent on the dose of irradiation. Table 2 demonstrates that the thymus of rats irradiated with as little as 50 r. differs significantly from that of controls.

The observed effect can be explained either by a break or weakening of some bivalent metal linkage

Table 2. YIELD OF DEOXYRIBONUCLEIC ACID IN EXTRACTIONS OF THYMUS 6 HR. AFTER WHOLE-BODY IRRADIATION WITH PHENOL-TRICHLORACETATE

Dose	Trichloracetic acid 0·5 per cent	Trichloracetic acid 1·0 per cent
Control	3·2 ± 0·41	8·47 ± 1·32
50 r.	7·8 ± 1·57	22·6 ± 1·64
100 r.	9·8 ± 0·43	29·4 ± 2·2
200 r.	16·9 ± 1·93	37·55 ± 3·03
400 r.	21·9 ± 0·6	53·6 ± 1·5
800 r.	22·8 ± 1·77	55·3 ± 6·74

Each value represents 9–18 animals. Yield (per cent) of the total acid.

between deoxyribonucleic acid and protein, as suggested by Kirby[4], or by a higher concentration of deoxypolynucleotides in the thymus. As the increase of deoxypolynucleotides has been observed only for a short period after irradiation[2], whereas the increased yield of deoxyribonucleic acid remains constant for a longer period, the first assumption seems more likely. To obtain further evidence on this point, nucleohistone was extracted from the thymus with 1 *M* sodium chloride, precipitated by dilution to 0·14 *M* sodium chloride and used for further treatment with phenol–trichloracetic acid. As will be published later in detail, a similar irradiation effect can be observed as in the whole organ. From thymus-nucleohistone, prepared from animals 6 hr. after 800 r., 50 per cent of the deoxyribonucleic acid is extracted in 0·5 per cent trichloracetic acid, whereas from nucleohistone of normal animals, only 10 per cent deoxyribonucleic acid can be obtained in 0·5 per cent trichloracetic acid. This indicates a labilization of the deoxyribonucleic acid from the protein, probably due to a break in bivalent metal linkages.

This labilization occurs in an early post-irradiation period, that is, 1–6 hr. after irradiation. Histological observations demonstrate death of some cells at this time, although the weight of the organ and the deoxyribonucleic acid content per gm. of tissue begin to decrease later, namely, 6–10 hr. after irradiation. It seems probable that the labilization of deoxyribonucleic acid from protein occurs prior to histologically observable death of a cell. The distinct lag period of 1 hr. before labilization begins, however, suggests that some other processes in the nucleus are involved with it or responsible for it. In particular, the possibility must be investigated of a preliminary degradation of the deoxyribonucleic acid chain.

I am indebted to Dr. R. N. Feinstein, of the Argonne National Laboratory, Lemont, Illinois, for helpful comments and corrections of the text.

Localization of a Halogenated Porphyrin in Mouse Tumours

SCHWARTZ *et al.* observed that certain commercially obtainable hæmatoporphyrin preparations were contaminated by a porphyrin capable of becoming localized in experimental tumours[1,2], and that pure hæmatoporphyrin was unable to do so. These findings gave the impetus to the present work on halogenoporphyrins. The premise on the basis of which halogenoporphyrins were chosen was the assumption that the aforementioned impurity represents an intermediate formed in the course of the synthesis of hæmatoporphyrin from hæmin. One such intermediate could be *bis*-(2-bromo-ethyl)deuteroporphyrin. Since iodine-131 is a more convenient isotope for the purpose of labelling than isotopes of bromine, the iodine-131–labelled analogue was synthesized.

When given parenterally, *bis*(2-iodoethyl-^{131}I) deuteroporphyrin became localized selectively in transplanted adenocarcinomata of *Dba*1 mice and in spontaneous mammary adenocarcinomata of *C3H* mice. This conclusion is based on the following experimental findings. All tumours when examined 6 hr. after injection or later exhibited the red fluorescence characteristic of porphyrins; the fluorescence was non-uniformly distributed within these tumours. In contrast, none of the other tissues exhibited this phenomenon. Although extracts of organs from mice injected with *bis*(2-iodoethyl-^{131}I)deuteroporphyrin contained no porphyrins, radioactivity, probably due to products of porphyrin catabolism, was found to be present. When tumours or other tissues were extracted with a mixture of ethyl acetate/acetic acid (4 : 1, v/v), only the extracts of tumours contained detectable amounts of a single porphyrin. This porphyrin was identical with *bis*(2-iodoethyl-^{131}I)deuteroporphyrin with respect to its specific radioactivity. Furthermore, when the aforementioned tumour-extracts were chromatographed on paper strips and the developed chromatograms scanned for radioactivity, the radioactivity of the porphyrin-containing spot accounted for all the activity initially placed on the strip.

When sections prepared from a transplantable mammary carcinoma were examined after fixation in formaldehyde and after removal of paraffin with benzene, fluorescence typical of porphyrin was observed within the tumour cells. In the limited number of observations made, fluorescence was found to be present only in intact tumour cells.

The mechanism underlying the selective accumulation of *bis*(2-iodoethyl-^{131}I)deuteroporphyrin in the tumours studied remains to be established and is now being investigated.

Synthesis of Diphosphopyridine Nucleotide in Irradiated Rats

WHEN suspensions of nuclei from thymus or spleen are incubated *in vitro*, adenosine monophosphate in the nuclei is phosphorylated to the triphosphate[1]. This phosphorylation appears to be abolished following low doses of X- or γ-radiation, given either *in vitro* or *in vivo*[2]. However, the net synthesis of diphosphopyridine nucleotide *in vivo* following intraperitoneal injection of 0·5 gm. nicotinamide/kgm. (ref. 3) was not abolished when rats were exposed to X-radiation in doses up to 1,500 r. 3–60 min. before nicotinamide injection (Table 1); in these experiments, the pyridine nucleotide content of the tissue extracts was measured by the alcohol dehydrogenase method[4]. Since the synthesis of this nucleotide is restricted to the nucleus of the cell[5] and

Table 1. INCREASE IN CONCENTRATION OF DIPHOSPHOPYRIDINE NUCLEOTIDE (DPN) IN RAT TISSUES 2 HR. AFTER INJECTION OF NICOTINAMIDE

Tissue	Increase in concentration (μmol. DPN/100 gm. tissue)	
	Control	After exposure to 1,500 r.
Liver	135·0 ± 6·9	124·0 ± 12·5
Spleen	21·3 ± 1·4	20·1 ± 1·3
Thymus	8·4 ± 0·7	8·1 ± 1·5

requires adenosine triphosphate[4], the above result suggests that appreciable amounts of adenosine triphosphate are still available to the cell nuclei during the first two or three hours after irradiation.

The absence of phosphorylation *in vitro* following irradiation[5] might be due to diffusion of nucleotides and other water-soluble materials, for example, catalase[5], from the irradiated thymus and spleen nuclei into the suspending medium. An analogous loss of nucleotides and soluble enzymes does in fact occur during the isolation of nuclei from non-irradiated liver cells[7] and is probably responsible for the reported absence of nucleotide phosphorylation from suspensions of normal liver nuclei[2].

HÆMATOLOGY

Isolation of Material with Proactivator Activity from Human Serum

IN the scheme proposed by Astrup[1] to represent the stages in the activation of human plasminogen to plasmin by streptokinase, the substance designated 'proactivator' has hitherto been a hypothetical one, postulated to account for certain observations made by Astrup and his co-workers, but never isolated by them. American workers, notably Sherry *et al.*[2], have doubted the existence of proactivator, pointing out that all procedures available for the purification of human plasminogen result in parallel purification of the proactivator activity. Ablondi and Hagan[3] think that proactivator and plasminogen are probably identical.

By a process of acidification of serum to pH 3·3, followed by ether extraction after neutralization, we have obtained material ('A.E.S.') which has powerful proactivator activity but has no activator activity and contains no plasminogen.

We have found Astrup and Mullertz's[4] bovine fibrin plate method convenient for studying this material. Spotted on the fibrin plates by itself, it produces no lysis of the fibrin, that is, it does not activate the bovine plasminogen present in the fibrin, nor is it of itself proteolytic. On addition of streptokinase to the material, however, it causes marked lysis of bovine fibrin (Fig. 1). This activated material is not proteolytic for casein, showing that plasminogen is absent. Further proof that plasminogen is absent is given by the fact that addition of urokinase does not result in the appearance of proteolytic activity which would occur if plasminogen were present, as urokinase is a direct activator of plasminogen.

The bulk of the proactivator activity is precipitated by 40 per cent saturation with ammonium sulphate. The material obtained forms a very fine suspension on dialysis against distilled water, and does not go into solution on adjusting the salt concentration to 0·15 M sodium chloride. However, the greater part of the activity dissolves in borate (0·05 M) buffered saline at pH 7·4.

Following activation with streptokinase, the activator activity is also precipitated by 40 per cent saturation with ammonium sulphate, but the activator precipitate is highly soluble in borate (0·05 M) buffered saline pH 7·4.

Proactivator prepared in this way is an extremely stable substance, withstanding boiling at pH 1·5 for 30 min. without loss. Preliminary data suggest it is a cholesterol-containing protein. Activator is much less stable than proactivator, and is most stable in the pH range 6·0–9·0. 50 per cent of its activity is lost at pH 7·5 in 3 hr. at 37° C.

Tentatively, it is suggested that proactivator is activator bound to an inhibitor, the inhibitor being cholesterol or a lipoprotein containing cholesterol. This may provide support for the hypothesis that lipoproteins have an inhibitory effect on fibrinolysis[5] and an explanation of the observed inhibition of fibrinolysis by alimentary lipemia[6].

Thanks are due to the director of the South African Institute for Medical Research (Dr. James Gear) and to the deputy director (Prof. J. F. Murray) for their encouragement and help in this work. Thanks are also due to Dr. A. Zoutendyk of the Serum Laboratories for abundant supplies of human serum, to Dr. J. Ploug (Leo Pharmaceuticals, Copenhagen, Denmark) for a generous gift of urokinase and to Mr. M. Ulrich for the photograph. This work was carried out with financial aid from the Council of Scientific and Industrial Research, Pretoria,

Serum Iron and Total Iron-binding Capacity in Certain Mammals

DATA in the literature concerning transport of serum iron in animals are very sparse, especially those which may be directly comparable.

In previous work[1], we studied serum iron in six species of mammals and in hens.

It is well known how iron travels bound to a fraction of β-globulins (siderophilin or transferrin), and how its concentration in serum may be expressed as the maximum quantity capable of being bound (total iron-binding capacity). In man it amounts to about 340γ per cent[2] and in absolute values it represents 0·2–0·32 gm. per cent proteins[3]. Human serum normally shows its siderophilin saturated only to 30–40 per cent, while in pathological cases extreme values may occur. In certain conditions (pregnancy, ferropenia, etc.) the content of siderophilin is also clearly increased.

We have studied serum iron and the total iron-binding capacity in eight mammal species, human included, using Ramsay's techniques[4,5] and the results obtained are given in Table 1. The differences between average values have been submitted to a test of statistical significance (Student's *t*).

Thanks to statistical analysis it has been possible to show that serum iron does not show any intersexual or interspecific differences which are significant. But it must be pointed out that an intersexual difference in sheep is significant; however, we must disregard it for want of homogeneity in the ages of the males.

On the contrary, in the values regarding the total iron-binding capacity, there exist evident differences between species. The comparisons between sexes in each species have not proved statistically significant, and for this reason the values for males and females have been mixed up in order to carry out the interspecific comparison.

The values for total iron-binding capacity in the porcine species give an average of 476·8γ per cent, which proves statistically significant when compared with the other species.

We may also point out the low values obtained in donkeys, with an average of 263γ per cent which is also significant as regards the other species, except in mules. Goats have given, however, the lowest values (233γ per cent), but due to the lack of data about the males, goats have not been included in the comparison.

The differences between the average value of the total iron-binding capacity for cows and man, and for man and mule, are also significant.

A comparison between species of the corresponding saturation coefficient for serum iron proves significant only in the case of porcine species.

We therefore have a series of mammals, several of which show specific values of total iron-binding capacity, although their serum iron cannot be statistically differentiated. These differences in the total iron-binding capacity must be attributed either to quantitative variations of a definite siderophilin or to the existence of specific siderophilins, which would not constitute any exceptional fact if we

Table 1. AVERAGE VALUES FOR SERUM IRON, TOTAL IRON-BINDING CAPACITY (TIBC) AND SC* WITH CORRESPONDING EXTREME VALUES, TYPICAL DEVIATIONS AND ERRORS OF THE AVERAGE FOR THE SPECIES CONCERNED, WITH SEPARATION OF SEXES, SHOWING NUMBER OF SPECIMENS IN EACH GROUP

Chromatography of Blood Thrombokinase on 'DEAE'-Cellulose

THROMBOKINASE, prepared from bovine plasma, has been obtained in a highly purified state by repeated electrophoretic fractionations[1]. However, a more efficient method was promised by anion-exchange chromatography, provided that the kinase could be separated from its accompanying impurities by stepwise elution in one day[2].

Fig. 1 illustrates an exploratory experiment in which purified kinase[3] from 21 litres of plasma was applied to a column of 2 gm. 'DEAE'-cellulose. Thrombokinase emerged in the last major band to be eluted by a series of potassium phosphate solutions. This opened up the possibility of recovering the kinase without appreciable dilution, if it were displaced by a strong eluant after protein impurities had first been removed by a weaker eluant. Such an experiment is presented in Fig. 2, where more than 90 per cent of the kinase in the original 19·2 ml. was recovered in the 20·5 ml. of the two best fractions. This was the product from 19·2 litres of plasma. Protein was estimated by the method of Lowry *et al.*[4]; and the total recovery was 91·3 per cent of the 44·4 mgm. put into the column.

The thrombokinase so obtained was diluted for some tests and dialysed for others, to avoid interference by phosphate. It could activate prothrombin in the presence of oxalate[5]; but it was much more effective when accompanied by calcium, cephalin and bovine barium carbonate-treated serum. In the latter system, the peak kinase fraction of Fig. 2 was assayed at a dilution of 1 to 1,200,000, corresponding to a protein concentration of 0·00088 μgm. per ml. The kinase activity of the fraction was 103 times that of the working standard. Because of the high dilution, and for other reasons[3], the assay cannot be considered precise. Nevertheless, the coincidence of protein and kinase data in the second band of Fig. 2 suggests an approach to homogeneity.

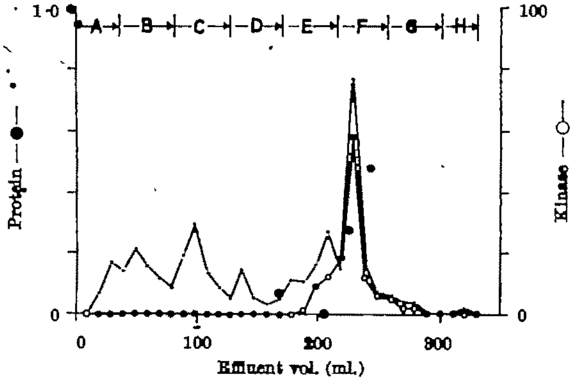

Fig. 1. Exploratory chromatography of thrombokinase. 4° C. Flow-rate 55 ml. per hr. *A*, thrombokinase in veronal, ionic strength 0·02, pH 8·6; *B*, 0·025 *M* phosphate, pH 7·84; *C*, 0·05 *M* phosphate, pH 7·88; *D*, 0·1 *M* phosphate, pH 7·88; *E*, 0·2 *M* phosphate, pH 7·90; *F*, 0·4 *M* phosphate, pH 7·95; *G*, 1·0 *M* phosphate, pH 8·20; *H*, 0·3 *M* phosphate, pH 4·40

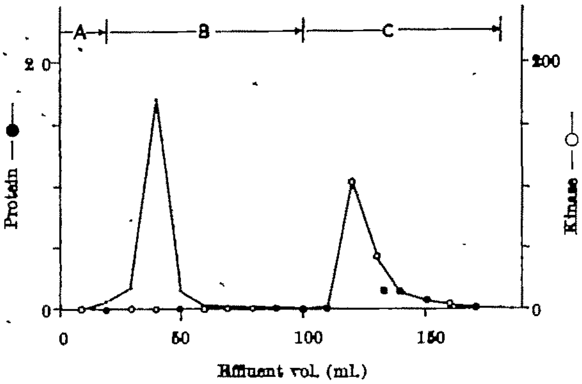

Fig. 2. Simplified chromatography of thrombokinase. 2 gm. 'DEAE'-cellulose. Column 1 cm. diam., 15 cm. high. 4° C. Flow-rate 27 ml. per hr. *A*, Thrombokinase in veronal, ionic strength 0·02, pH 8·6; *B*, 0·1 *M* phosphate, pH 7·88; *C*, 1·0 *M* phosphate, pH 8·20

This suggestion is furthered by a comparison with the results of continuous-flow paper electrophoresis. In a third serial run by that method, almost all the protein appeared in a single peak[1]. There was a close correspondence of the data for protein and kinase, and also for tosyl-arginine methyl ester esterase, indicating that tosyl-arginine methyl ester is a substrate for thrombokinase. For the five chief fractions, the data for esterase units[6] per mgm. protein were 329, 359, 338, 333 and 325, with an average value of 337. Corresponding data for the two chief kinase fractions of the present Fig. 2 were 349 and 345. Although the agreement is good, further tests for homogeneity will be desirable, particularly since the present method was designed for preparative isolation rather than analysis. For the present, it may be noted that about the same amount of thrombokinase at this degree of purity was obtained in the experiment of Fig. 2 in one day as was previously obtained by electrophoresis, applied to the product from 738 litres of plasma over the course of several weeks.

Tosyl-arginine methyl ester esterase also occurred in the first band of Fig. 2; but this was associated with thrombin, which was found in the first band but not the second. Thus, the procedure separated thrombin from thrombokinase. In harmony with the findings of others[6], the tosyl-arginine methyl ester esterase associated with thrombin was not inhibited by crystallized soy bean trypsin inhibitor at a concentration of 1 mgm. per ml.

In parallel tests, the tosyl-arginine methyl ester esterase of the kinase band was mostly, but not quite entirely, inhibited. It has previously been shown that the trypsin inhibitor suppressed activation of prothrombin by blood thrombokinase in the presence of oxalate[7]. The general anti-thromboplastic effect of the inhibitor in the presence of calcium has long been known[8]; and recently it has been reported[9] that thromboplastin-generating systems exhibited tosyl-arginine methyl ester esterase activity which was markedly inhibited by soy bean trypsin inhibitor.

It appears that thrombokinase, as described here, is an enzyme with some resemblances to trypsin. Its properties offer a unifying correlation for many diverse observations. The manner in which cephalin or platelet material augments the effect of thrombokinase is not completely understood. However, it is well to recall the suggestion of Macfarlane[8]: "It is possible in fact that cephalin, supposed by various workers to represent 'pure thromboplastin', is no more than a cofactor with calcium and a proteolytic enzyme (thrombokinase), potentiating the digestion of prothrombin and consequent release of thrombin".

Nadia Oulianoff, Harriet F. Brown and Thomas R. Saxton assisted in this investigation, which was supported by Research Grant *H* 3906 from the National Heart Institute, U.S. Public Health Service.

PATHOLOGY

Mast Cells and 5-Hydroxytryptamine in Precancerous Mouse Skin

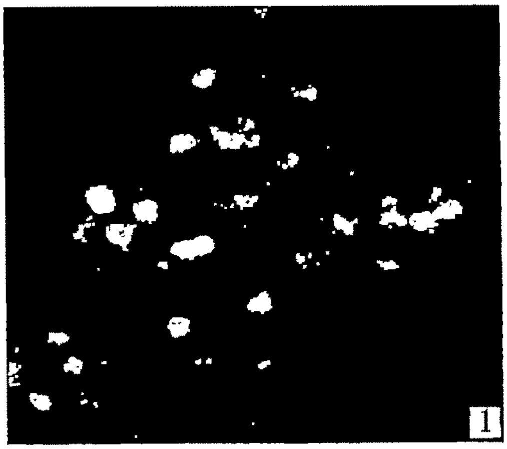

Fig. 1. Fluorescent mast cells at base of mouse skin papilloma. (× 400)

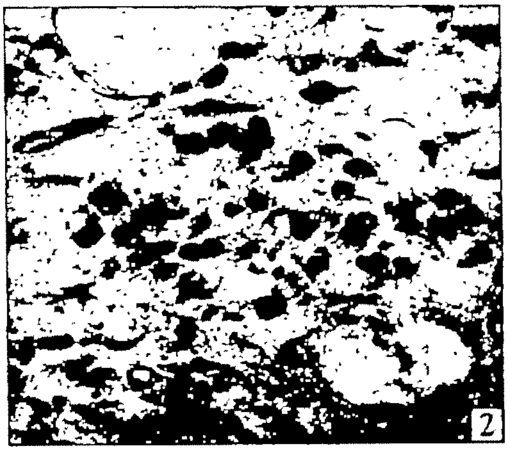

Fig. 2. Same field stained with toluidine blue. (× 400)

A CURIOUS feature of carcinogenesis in the skin of the mouse is the intense mast-cell reaction which gradually develops in the dermis immediately under the painted hyperplastic epidermis. Cramer and Simpson[1] observed that some of these new mast cells exhibit a golden-brown fluorescence in ultra-violet light, providing that the frozen section has also been treated with formaldehyde.

Mast cells in the mouse (and rat) normally contain not only histamine[2] but also 5-hydroxytryptamine[3]. Riley[4] suggested that the golden-brown fluorescence exhibited by some mast cells, in formol-fixed sections, may indicate an abnormally high content of 5-hydroxytryptamine.

Attempts to localize the 5-hydroxytryptamine in pre-cancerous mouse skin by direct assay of tissue slices, though giving only a rough guide to the location of the amine (Cass and Riley, unpublished work), suggest that it occurs predominantly in the upper dermis. In the present work, histochemical methods applied to sections of precancerous mouse skin demonstrate with precision that the 5-hydroxytryptamine is concentrated in the granules of those mast cells which exhibit primary fluorescence in sections in fixed formol.

The dorsal skin of albino mice (Tucks) was painted on two occasions seven days apart with 0·5 per cent 9 : 10-dimethyl-1 : 2-benzanthracene dissolved in acetone. Animals which developed ulceration of the skin were discarded: the remainder recovered almost completely from an initial epilation and gradually developed papillomas or carcinomas over the next eight months. Animals were killed at varying intervals by cervical dislocation. The skin was fixed in formol–saline, formol–calcium or formol–dichromate buffered to pH 6. Frozen and paraffin sections were examined either in ultra-violet light (Leitz primary filter, 4 mm. *U.G.*1, secondary filter 2·5 mm. Euphos.) for fluorescence or in visible light after staining with

Table 1

	Chromaffin reaction	Toluidine blue	New methylene blue	Alkaline diazonium	Indophenol	Schmorl	Fluorescence

+ + +, Strong reaction; –, no reaction.

one of the following methods: toluidine blue, New methylene blue, diazo-coupling with Garnet *GBC* salt or fast red *TR* at *p*H 9·2, treating with 2 : 6-dibromoquinonechloroimide (indophenol reaction[5]) or with Schmorl's ferri-ferricyanide mixture[6]. The most sensitive histochemical method, though not entirely specific for 5-hydroxytryptamine, was the Schmorl reaction applied to formol–calcium-fixed sections. However, it was often possible to apply more than one technique to the same section and so demonstrate convincingly that the specific staining reactions, described below, do occur in mast cells and not in other types of dermal cells with cytoplasmic granules. The results, which will be published in detail elsewhere, are summarized in Table 1. The methods referred to, except the chromaffin reaction, were all performed on formol–calcium fixed material.

The above findings, together with the results of direct assay (Cass and Riley, unpublished work), indicate that 5-hydroxytryptamine is concentrated in the mast cell granules. The number of positive cells increases during the induction period. A strongly positive reaction is most commonly seen in mast cells at the base of papillomas (Figs. 1 and 2), though a positive mast cell is occasionally seen elsewhere in the treated dermis. It is thus clear that the high level of 5-hydroxytryptamine in precancerous mouse skin is due not only to an increase in the number of mast cells in the area but also to a progressive increase in content of 5-hydroxytryptamine in certain of these cells.

A Transplantable Spontaneous Osteogenic Sarcoma observed in the Muscle Tissue of an Albino Mouse

OSTEOGENIC sarcomas attached to bone tissue have been reported in animals of different species. In 1936, Brues[1] described a case of spontaneous osteogenic sarcoma in the jaw of a three-year-old grey rabbit. Barrett *et al.* reported an osteogenic sarcoma attached to the left femur of a *C3H* female mouse[2]. Osteogenic sarcomas have also been induced by radioisotopes such as radium-226, strontium-90, calcium-45 (ref. 3) and strontium-89 (ref. 4). One case of osteogenic neoplasm arising from muscle tissue has been reported in man[5]. This tumour found in the thigh muscle had developed over a period of ten years and was believed to have followed an abscess in the muscle.

The tumour to be described was found in the soft tissue of the lateral neck region of a full-grown female mouse from our breeding colony. This colony was derived from *CF*1 mice of Carworth Farms. The host was a multiparous mother approximately six months of age. The neoplasm was situated between the muscle layers of the right sternohyoideus and sterno-cephalicus muscles and the skin. It was approximately 1 c.c. in volume. This tumour has been designated *H*-7. An attempt was made to transplant it into the same strain of mouse as the host. The neoplasm was excised and macerated in a sterile mortar, adding an equal amount of normal sterile physiological saline. An injection of 0·1 ml. of the suspension was made into the subcutaneous tissues of the right hind leg of 5 male and 5 female mice. A satisfactory growth was obtained in 6 of the 10 mice of the first generation. At eight weeks tumour tissue was removed from these mice for a second transplantation using aseptic technique. Suspensions of the first-generation tumour found to be microbiologically sterile were injected into 16 male and female mice of the same strain. The growth-rate of the second generation tumour was increased and the tumour-take was 100 per cent. The tumour was removed at six weeks for resuspension and injection into the third generation.

Histologically the tumour presented the classical picture of osteogenic sarcoma with abundant bone formation. It is apparently as difficult to determine the exact site of origin of osteogenic sarcomas in animals as in man. The primary tumour in this case did not seem to have grossly an intimate fusion with bone. For this reason, the actual site of origin of the tumour is uncertain. Studies are at present being made of the cytology, histology and enzymatic characteristics of *H*-7 as well as its transplantability in homogeneous and heterogeneous host animals, detailed results of which will be published later.

Treatment of *Leishmania donovani* Infections with Surface-active Agents

'TRITON *W.R.* 1339', an arylalkyl polyoxyethylene ether of phenol, prepared by Rohm and Haas Co., Philadelphia, is a non-toxic surface-active agent, and was shown to exert a suppressive effect in experimental tuberculosis of mice[1]. 'Macrocyclon' is the polyoxyethylene ether containing on average 12·5 ethylene oxide units per chain, formed by reaction of ethylene oxide with a macrocyclic phenol and possesses similar antituberculous activity[2].

In view of these favourable results obtained, it appeared that the same drugs might be of value in treating other infections, such as kala-azar, in which development of the infecting agent also occurs in the white cells of the host.

Twenty golden hamsters were infected intraperitoneally with a strain of *Leishmania donovani* isolated from an Indian seaman and afterwards maintained by passage in these animals in which the infection is invariably fatal[3]. Six weeks later, biopsies were made and the number of parasites per oil immersion field determined in smears of spleen. Intraperitoneal treatment with the two drugs named above in dosage of 125 mgm. was given on days 2, 5, 9 and 15 after biopsy to groups of six animals and a similar number of untreated animals were used as controls. They were killed three weeks later and counts were again made of the number of parasites in spleen smears. Although no cures had been effected the results indicated that the drugs had controlled the infection.

A second experiment was carried out in which thirty hamsters were infected as before. Treatment with 125 mgm. drug per animal was started on the day of infection and repeated 2, 6 and 9 days later. Five animals received similar treatment with each drug in absence of infection and survived. The infected animals were killed 8 weeks later and parasite-counts were made in smears of spleen. The results obtained are shown in Table 1.

Table 1. *Leishmania donovani* BODIES PER OIL IMMERSION FIELD

In a further experiment thirty hamsters were infected and intraperitoneal treatment with 125 mgm. of each drug was given 4, 7, 11, 14, 18 and 20 days later. The animals were killed 7 weeks after infection. Five uninfected animals received similar treatment with each drug and survived. The results obtained are shown in Table 2.

Table 2. *Leishmania donovani* BODIES PER OIL IMMERSION FIELD

BIOLOGY

Delayed-type Hypersensitivity in Premature Neonatal Humans

IT has been shown[1] that guinea pig embryos could be induced to develop the delayed-type of hypersensitivity[1]. The possibility that the premature new-born human could be similarly sensitized was therefore investigated. Successful sensitization of new-born humans to poison ivy has been reported[2].

Ten premature infants (average birth-weight 1,255 gm.) and five neonatal infants of normal weight were sensitized percutaneously during the first week of life with 0·02–0·04 ml. of a 10 per cent solution of 2,4-dinitrofluorobenzene in acetone. As controls, five infants between the ages of 2 and 12 months were similarly sensitized. 2–4 weeks later patch-testing was carried out with 0·01 molar 2,4-dinitrofluorobenzene in corn oil–acetone. The patches were removed at 48 hr., at which time the reactions were read.

Table 1. CONTACT SENSITIVITY TO 2,4-DINITROFLUOROBENZENE IN HUMAN INFANTS

Group	Contact reactions	
	2 weeks*	3–4 weeks*
Infant (2–12 months)	5/5	Not done
Full-term neonatal	1/4	2/5
Premature neonatal	2/10	3†/10

* Time after sensitization.
† Birth-weights were 1,390, 1,060 and 1,650 gm. The first two of these infants received two sensitizing doses nine days apart.

As can be seen in Table 1, this sensitization procedure induced contact skin reactivity in all five of the older infants, two of five normal neonatal infants and three of ten premature new-born infants. The positive reactions of the neonatal infants appeared similar to those elicited in the older infants, but were usually less intense. There was no detectable relationship between the weight of the premature neonatal infant and its capacity to be sensitized. This is strikingly illustrated by one of the smallest infants in the experiment, who weighed 1,080 gm. at birth (indicating a gestation period of approximately 30 weeks) and yet showed a contact reaction at age three weeks. Moreover, the neonatal infants of normal weight did not appear to become sensitized any more readily than did the premature new-born infants.

Punch biopsy of a representative contact reaction at 48 hr. was performed in a premature infant. Histological examination of serial sections revealed an accumulation of lymphocytes and histiocytes in the dermis with invasion of the epidermis and resultant

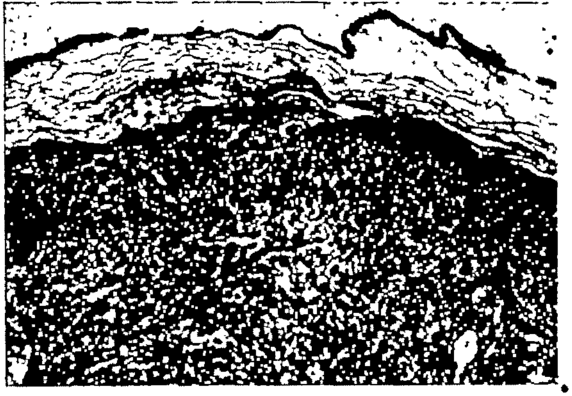

Fig. 1. Contact reaction at 48 hr. in a premature neonatal infant, three weeks of age. Hematoxylin and eosin. (× 200)

loss of the basement membrane (see Fig. 1). Microvesicles, spongiosis and an increase in mitosis were seen in the epidermis. The histology is consistent with that seen in contact dermatitis in the adult[3]. Patch testing 2–6 weeks after birth of unsensitized neonatals (six premature and six full-term) gave negative results. Punch biopsy with histological examination of a patch test area at 48 hr. in an unsensitized premature neonatal, aged three weeks, also failed to show an inflammatory reaction.

Our findings show the following striking similarities to previous work on antibody formation in new-born infants[4]: (*a*) delayed-type hypersensitivity and antibody formation can both be induced in premature infants during the first month of life; (*b*) new-born infants are inconsistent in their capacity to develop these two types of immune response; (*c*) premature infants become sensitized and form antibodies as efficiently as normal new-born infants.

This work suggests that the older human fœtus might be capable of an immune response if an appropriate antigenic stimulation could be administered *in utero*. The possibility is not excluded, however, that separation from the placenta is an essential step in the maturation of the immune mechanism.

We thank Dr. Philip Prose, of the Department of Pathology, for his assistance in the processing and interpretation of the skin biopsies.

This work was aided by grants from the Association for the Aid of Crippled Children, the National Institutes of Health (*E* 1821 (*C*-2)) and the Commission on Immunization of the Armed Forces Epidemiological Board.

The Polychæte Family Longosomidae in New Zealand

IN 1944 Hartman[1] described a new polychæte species *Longosoma catalinensis* from off Long Point, Catalina Island, southern California, founding a new family, the Longosomidae, to contain it. The original description was based on a single specimen, but afterwards in 1957 she reported 34 specimens from three stations off southern California in depths of 7–45 fathoms. According to Hartman[2] the species may have its affinities with the Paraonidae; but the possession of long, paired, grooved palpi, resembling those of spioniform annelids, allies it to the disomid and magelonid families.

The genus and family have not been recorded to date from other than the original locality, hence it was of great interest to obtain specimens of a polychæte, which at first were thought to be specifically identical with *L. catalinensis*, from such a distant locality as Hawke's Bay, New Zealand. The New Zealand specimens, numbering 27, were obtained in August 1956 from twelve stations, in depths of 8–64 fathoms, by Dr. D. Hurley of the New Zealand Oceanographic Institute, and I am indebted to him for the opportunity to report on this interesting discovery. On a recent visit to California, the New Zealand specimens were compared with the type of *L. catalinensis* and Dr. Hartman agrees that the differences justify the founding for them of a new species of the genus *Longosoma*. As in *L. catalensis* they have the body divided into an anterior region of nine short setigerous segments and an abdomen with greatly prolonged cylindrical segments, the abdominal parapodia consisting of ridges with double rows of simple setæ. The New Zealand species differs in its larger size, the largest posteriorly incomplete specimen of *L. catalinensis* with four abdominal segments measuring 25 mm., whereas a comparable specimen of the former measures 55 mm. They are also much more robust, with the thorax measuring up to 3 mm. across, and with the thoracic setæ heavier and more numerous. The proportionate length of the abdominal segments also differ, but the greatest difference is to be seen in the arrangement of the abdominal parapodia. In *L. catalinensis* the abdominal parapodia are low ridges encircling two-thirds to three-quarters of the body and leaving the ventrum plain, while in the New Zealand species the ridges are much more prominent and completely encircle the body. A full description of the species will be published separately.

It is of interest to note that Hartman records her specimens from similar depths in very fine sand and silt and in temperatures of about 14·9° C. The bottom sediments from the stations where the New Zealand specimens were obtained are recorded as ranging from fine grey sands to fine sandy muds with bottom temperatures in the region of 13·0–13·3° C. According to Hartman, *L. catalinensis* is associated with other polychætes, a maldanid, *Axiothella rubrocincta* (Johnson) and a nephthyid *Nephthys ferruginea* Hartman, and a cumacean, probably *Diastylopsis tenuis* Zimmer. Some thirty-six species of polychætes have been recorded from Hawke's Bay in association with *Longosoma*, among the dominant being a nephthyid, *Aglaophamus verrilli* (McIntosh), and two species of maldanids of the genus *Asychis*. Other dominants include the cumaceans *Diastylopsis elongata* Calman and *D. crassior* Calman (belonging to the same genus as the cumacean associated with *L. catalinsis*), the holothurian *Cucumaria ooonoides* (Dendy), ophiuroids of the genus *Amphiura* and the bivalves *Dosinia lambata* (Gould) and *Maorimacta ordinaria* (Smith).

The present recorded distribution of the family Longosomidae, southern California and northern New Zealand, represents a very disjunct distribution. In both localities the representatives of the family are not uncommon, and it is therefore surprising that it has not been recorded elsewhere. Additional distributions will, however, probably be recorded when similar shallow bottom areas of the Pacific basin are studied in detail, as has been done for the areas off southern California and Hawke's Bay, New Zealand. It is of interest that similar techniques were used in processing the bottom samples from the two regions. A similar disjunct distribution is recorded for the species of the echiuroid genus *Urechis*, which has been recorded from southern California, southern Chile, New Zealand, and Japan[3].

Mouth and Blastopore

By the Haeckelian view of early development, gastrulation by invagination reflects the evolutionary history of primitive Metazoa. It is a corollary of this theory that gastrulation by ingression is a derived form of emboly. Nevertheless ingression, the method of endoderm formation among the lower cnidarians, is probably the more primitive mode of gastrulation, as observed by Metschnikoff[1,2], Hyman[3,4] and others. The diploblastic level of organization probably arose in early Metazoa by a process resembling ingression, or some other type of delamination, giving rise to solid planula-like forms. It is therefore probable that invagination is merely a developmental expedient, which has arisen secondarily and independently in the more advanced Cnidaria and other metazoan groups.

The blastopore results from invagination, narrowing as gastrulation progresses. In keeping with Haeckel's interpretation, it is generally thought to represent the primitive mouth. It may nevertheless be merely a product of the mechanics of development, without especial phylogenetic significance. The Cnidaria in which gastrulation occurs by ingression, while possessing a mouth and coelenteron, have no blastopore or archenteron during development. It appears from the embryology of these coelenterates that mouth and blastopore were independently acquired in early Metazoa. Furthermore, a mouth may have formed before the origination of embolic gastrulation and a blastopore. Following the evolution of embolic gastrulation, the blastopore preceded the mouth in embryonic development, for it relates to the fundamental process of germ-layer formation. Similarly, it appears that enteron and archenteron were independently evolved. Terms such as protostoma, Protostomia and archenteron are therefore strictly inapt.

The mouth in some non-coelomate animals and Protostomia does not coincide with the blastopore or its point of closure. Also, in many higher coelenterates, non-coelomate groups and Protostomia the blastopore does not persist as a mouth, but closes before the mouth forms. This possibly signifies the evolutionary independence of the two structures.

It is generally agreed that the embryonic axis corresponds with the polar axis of ancient Metazoa, the animal pole representing the primitive perceptive and dominant region, directed forward in locomotion. Biologists who support the ingression theory, but identify the blastopore with the primitive mouth, believe that the mouth arose at the more inert end in a solid, diploblastic ancestral metazoan. This entails the puzzling conception of a structure for the selection and ingestion of food separated from the dominant, sensitive region of the body. It seems more probable that the mouth originally occupied an antero-ventral position.

In coelenterates the mouth typically forms at the posterior end of the swimming larva, in the blastoporal region when gastrulation is by emboly, and does not change position during development. This may be a special feature correlated with the sessile habit of the polyp.

Typically, in cases of gastrulation by invagination, the gastrula presents two centres of high metabolic activity of different kinds: the animal pole, corresponding with the controlling and perceptive region of original Metazoa and larval forms; and the blastopore, a zone of rapid cell division, and a focus of developmental activity and organization. Among the Protostomia, the mouth arises in the blastoporal field, later coming to occupy an antero-ventral position. The mouth thus develops in a region of high formative activity, and may form from the blastopore, a ready-made aperture. This may be merely a developmental convenience. (By a similar short cut in development, in some Protostomia and Deuterostomia a persistent blastopore forms the anal opening.) In the embryonic development of many annelids, the blastopore elongates and constricts into two. One of the apertures so formed, the mouth, separates to its definitive ventral anterior position. The second aperture, remaining at the vegetal pole, soon closes. The anus later arises at this point. The division of the blastopore has been interpreted as separation of the mouth from a transitory anal pore. It more probably represents dissociation of the mouth from the blastopore.

Among the Deuterostomia, the mouth typically originates at an antero-ventral point. This is believed to indicate that the mouth has evolved anew and assumed the function of the primitive mouth, homologous with the blastopore. It is more probable that the mouth in the Deuterostomia occupies the original position, and the blastopore at no time functioned as mouth.

Softening Chitin for Histology

The chitinous integument of many invertebrates consists not of chitin alone but also incorporates much structural protein. In the more highly sclerotinized arthropod shells, indeed, this may far exceed the true chitin. The methods frequently used for softening 'chitin' for histological purposes make use of this fact, and none of them actually alters the chitin itself, acting instead on the protein moiety of the integument. 'Diaphanol', for example, the most widely used agent for softening 'chitin', acts by breaking benzene rings in the aromatic amino-acid residues of the proteins[1]. Inevitably such an action is accompanied by extensive damage to the tissues of the specimen, for not only is the protein of the skeleton digested but also the proteins of the tissues which we wish to examine. The use of diaphanol, or of other agents which digest the protein moiety of the chitinous integument, is therefore incompatible with precise histological or cytological investigation. If the integument consists mainly of structural protein, then we have no way out of the dilemma except to dissect the tissues free from all traces of the offending shell. If, however, as in the less-sclerotinized shells, it consists chiefly of true chitin, then it is possible to attack the chitin enzymically, leaving the tissues untouched.

Possibly the best source of a suitable chitinase is the unripe puff-ball, *Lycoperdon* spp. Tracey[2] advocates this source of the enzyme for biochemical analysis. He suggests that the puff-balls should be torn up and pressed to yield a juice which, when buffered at pH 5 with acetate buffer, will readily digest chitin. This juice may be stored for a year or more in a refrigerator under toluene. I have used this extract for softening chitin for histological purposes, but it contains also a number of other enzymes which damage the tissues that are under examination. Moreover, puff-balls are not readily obtainable. The common mushroom of commerce also contains large amounts of chitinase, and may be obtained at any time of year. The extraction outlined below may be applied to either mushrooms or to puff-balls, and yields a liquid which will keep for a year or more in the refrigerator and is relatively free from other enzymes that might detract from its histological usefulness.

100 gm. mushrooms are roughly torn up and steeped overnight in 100 ml. 35 per cent w/v sodium chloride solution. The chitinase is soluble in this saline, while most of the other enzymes are salted out and are present in the residue which is centrifuged off. This stock solution may be kept in the refrigerator without the addition of any preservative, as the salt concentration is above the limit for bacterial or fungal growth. For use it is diluted to an appropriate salt concentration either with acetate buffer at *p*H 5 or more simply with distilled water, relying on the atmospheric carbon dioxide to produce approximately the correct *p*H. For marine organisms a dilution of 1 : 10 seems appropriate, giving a solution nearly isotonic with sea water. The fixed specimens are washed well with running tap-water overnight to remove the last traces of the fixative, which might inactivate the enzyme. They are then incubated with the diluted enzyme preparation for 12–24 hr. at 37°. A little toluene may be added to prevent bacterial action, particularly if the chitin is thick and it is desired to continue incubation for a longer period. After incubation the specimens may be prepared for sectioning in the usual way. This technique has proved successful with the copepod *Calanus*, the prawn *Palaemon* and the insect *Locusta*. It is useless with heavily sclerotinized integuments, which have a high protein content and low chitin content.

An Improved Feed for Experimental Fish

It is well known that minced liver is an excellent food for brown trout (*S. trutta*) kept under hatchery conditions or under experimental conditions in aquaria[1]. In aquaria with a low water-flow the minced liver very quickly fouls the water. It has been found that if the liver is mixed with gelatine this difficulty can be avoided. As many workers now use these fish as experimental animals, it is felt that it would be useful to publish this fact.

The minced liver, previously salted with 5 gm. of salt per pound of liver, is mixed with 120 c.c. of a 33 per cent solution of gelatine. The whole is allowed to set and then reminced before feeding.

Survival of Woody Plants at Extremely Low Temperatures

There are a number of things that should be pointed out in connexion with the communication by A. Sakai[1]. Various kinds of plant material have been cooled to these temperatures and even lower, yet they have survived[2–4]. My own work[5] revealed that leaves of *Pinus strobus* could be cooled to −90° C. in winter without apparent damage, and it was later shown that leaves of this same species could be cooled to −189° C. without damage as indicated by the tetrazolium test made several days after treatment[6,7]. Recently I have cooled buds of various deciduous trees to −80° C. at the rate of cooling and warming indicated in Table 1, and although some survived, others did not.

Table 1. Cold Resistance* of Tree Foliage in Deg. C. at New Haven, Connecticut, in January

Rate of cooling about 4° C. change per hr.; rate of warming about 8° C. change per hr. Most plants became still hardier in February

Plant	Origin	Resistance* ° C.
Abies guatemalensis†	Costa Rica	−6
Cupressus lusitanica†	Costa Rica	−10
Cryptomeria japonica	Japan	−20
Pinus palustris†	Northern Florida	−25
Ilex opaca	unknown	−35
Chamaecyparis pisifera	Japan	−42
Taxus baccata	unknown	−42
Tsuga canadensis	New Haven, Conn.	−45
Juniperus virginiana	Branford, Conn.	−52
Picea excelsa	Germany	−58
Tsuga canadensis	Branford, Conn.	−58
Pinus sylvestris†	Germany (?)	−62
Pinus strobus	New Haven, Conn.	> −189

* The lowest temperature which the leaves could withstand without being killed.

† Seedlings 1 to 6 years old.

I thus feel that Sakai's findings are generally in accord with my own and those of others. On the other hand, one gains the impression from Sakai's communication that if a plant can be cooled to −30° C. without damage it can be cooled on down far below this without any damage. Yet the winter resistance of several conifers can range all the way from a few degrees below freezing to below −189° C. (Table 1). But the rates of cooling and warming are most important in such work and should not be changed.

Finally, it should be understood that nearly any criterion of life or death can be at fault if not used in the correct way. Several days after the treatment is made, the tissue may die while controls survive. This error is particularly involved in plasmolysis tests which indicate the intactness of the outer vacuolar membranes but do not prove that the cytoplasm itself has not been injured. Judging by the tetrazolium test, enzymes may become less active over a period of time and finally show no activity, while untreated cells continue to reduce tetrazolium salts. The more severe the injury the more rapidly this change comes about after warming. In our experiments the time-lag effect in dying is a serious source of error in cold-treated leaves. Some leaves which survived in a moist chamber at 22° C. for two weeks died in the third week, while controls survived for at least three months.

[7] Parker, J., *Bot. Gaz.*, 121, 46 (1959).

JENSEN[1] has also claimed that the ability to plasmolyse in onion cells is not a reliable index to their viability, because he observed some abnormal cells in which vacuoles were normally stained by neutral red solution and tonoplasts still retained their permeability, having the cytoplasmic layers torn outside the tonoplasts. In a previous report[2] I stated that such abnormal cells have not yet been observed during several years study in the parenchyma cells of the cortex in woody plants, but some parenchyma cells are found in which the ectoplasts still retain their semi-permeability though their tonoplasts are torn and their cytoplasmic layers are mixed with vacuolar content (see plate1,2 ref. 2) However, such abnormal cells are easily distinguishable from the normal by their appearance. Thus, in the parenchyma cells in twigs of woody plants, unlike the case of onion cells, it may be possible to determine the relative degree of viability in parenchyma cells, upon the basis of both their vital staining with neutral red solution and the appearance of plasmolysed cells, at least in one and the same series of experiments. However, judging[3] of the intactness of twig as a whole cannot be made only on the basis of plasmolysis test in parenchyma cells just subsequent to, or even after, many days of thawing, because inner cortex, pith ray, and pith periclinal tissue are less resistant to freezing than parenchyma cells of cortex. Accordingly, to demonstrate the intactness of a treated twig as a whole, it was planted in moist sand and its capacity tested to continue normal development at least for three months after planting, as mentioned in my reports[4]. Even in the tetrazolium[5] test used by Parker, it may be said that judging the intactness in plants means only determination of a relative value of viability of certain tissues in twig or leaf without testing the whole of it as is done by the plasmolysis method.

In my previous communication in *Nature* (and ref. 4) it was stated that almost all the easily freezable water in a cell may be drawn from the cell interior by extracellular freezing at about −30° C., and that the cells and tissues in this state are not injured even when immersed directly in liquid nitrogen, provided they can sufficiently withstand such pre-freezing at −30° C. Moreover, it was reported that below this temperature the intensity of cold seems not to exert any important effect upon woody plants, at least as long as the intense cold does not extend over a long period. Against this view, Parker has pointed out that one gains the impression from my article that if a plant can be cooled to −30° C. without damage, it can be cooled down far below this without any damage. As a result of Parker's experiment the winter resistance of several conifers could range all the way from a few degrees below freezing to below −190° C.

In the pre-freezing method, to cool plant material to −30° C. does not mean that the temperature of the material only reaches −30° C., but that its material attains at least the state of equilibrium at −30° C. and the state in which almost all the easily freezable water in a cell is drawn from the cell interior. To assure this condition, in the case of freezing in comparatively large material as a twig, I pre-froze it for 16 hr. (overnight) in all cases as mentioned in previous papers[4,6]. In the cooling method used by Parker, when a certain temperature-level was reached in the flask containing a shoot from branch, the flask was removed from the chilling apparatus, then rewarmed. In such cooling method, even if plant material is cooled to −30° C., it is doubtful whether almost all the freezable water in the cell interior can be drawn out or not within such short period of time.

The grade of frost resistance of a woody plant differs according to the manner in which it is estimated. If the grade of frost-resistance is represented by the lowest temperature at which the twigs are able to survive freezing for an hour, especially when the cooling-rate in a temperature-range below −30° C. is comparatively slow as 4 deg. C./hr., there can be found fairly great differences in the grade of frost injury in the twigs treated at an arbitrary different temperature below −30° C. This is particularly the case of less hardy species. However, when the grade of frost resistance is represented by the minimum temperature at which the twigs are able to survive freezing for a full day, there is found, in many cases, scarcely any difference in the grade of frost resistance between the material treated at −30° C. and that at −70° C. (ref. 7). It may be said, therefore, that the discrepancy between our two points of view is due mainly to the difference in the manner of representation of the grade of frost resistance. However, to clarify this problem, it seems necessary to continue further work in many woody plants.

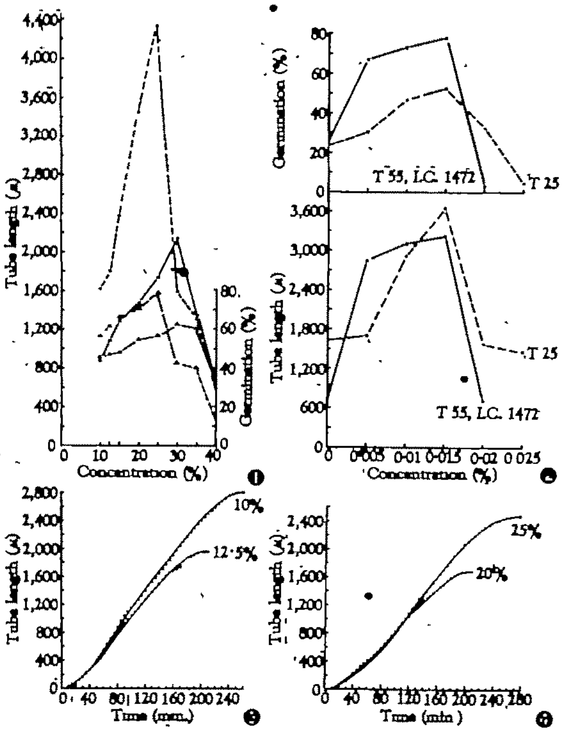
Pollen Germination in some Gramineae: *Pennisetum typhoideum*

POLLEN of grasses is notoriously difficult to culture, and even in Nature fertilization usually fails if pollen is not transferred directly from the anthers to the stigma[1,2]. Several previous attempts to germinate the pollen grains of the Gramineae have been unsuccessful[1–4]. In this laboratory attempts were made to germinate pollen grains of *Pennisetum typhoideum* (varieties *T*.25 and *T*.55, *I.C*.1472), *Zea mays* (*T*.41 var. Kanpur) and several varieties of *Hordeum vulgare*, *Sorghum vulgare* and *Triticum aestivum* by the hanging-drop technique (for details of technique see Vasil[7]). Best germination was obtained in *Pennisetum typhoideum*, while in the remaining plants pollen tubes longer than 600µ could not be obtained even after the addition of hormones, vitamins, mineral salts and stylar and ovarian extracts.

The pollen grains of *P. typhoideum T*.25 germinate within 10 min. of their inoculation in 10–40 per cent sucrose solutions and the optimum germination (62 per cent) occurs in 30 per cent sucrose where the tubes attain a length of 2,132µ (Fig. 1). With the addition of 0·01 per cent boric acid best growth is obtained in 25 per cent sucrose. In this medium 78 per cent of the grains germinate and the pollen tubes attain a length of 4,320µ (Fig. 1). Pollen grains of the variety *T*.55, *I.C*.1472 require lower concentrations of sugar: in 12·5 per cent sucrose there is 40 per cent germination and the tubes are 316µ long. Here also the percentage of germination is improved on the addition of 0·01 per cent boric acid, and



Figs. 1–4. *Pennisetum typhoideum*. Fig. 1, variety *T.*25, pollen germination and growth of tubes in different concentrations of sucrose supplemented with 0·01 per cent boric acid; for 3 hr. at 30° C. (——, without boric acid; – – –, with boric acid; ●, tube length; ▲, per cent germination). Fig. 2, varieties *T.*25 and *T.*55, *I.C.*1472, pollen germination and pollen tube growth in 25 per cent (*T.*25) and 12·5 per cent (*T.*55, *I.C.*1472) sucrose supplemented with different concentrations of boric acid; for 4 hr. at 29° C. Fig. 3, variety *T.*55, *I.C.*1472, growth curves of pollen tubes cultured in 10 and 12·5 per cent sucrose supplemented with 0·01 per cent boric acid; at 22° C. Fig. 4, variety *T.*25, same as in Fig. 3 but in 20 and 25 per cent sucrose with 0·01 per cent boric acid; at 18° C.

increases to 76 per cent while the tubes elongate to 3,125μ. The pollen tubes exhibit typical sigmoid growth curves (Figs. 3 and 4).

Among the various sugars tested, sucrose proved to be the best. In dextrose (with 0·015 per cent boric acid) the percentage of germination is 82, a figure higher than that in sucrose, but the length of the tubes is only 2,160μ.

The effect of boric acid is well marked in both the varieties (Fig. 2). In the pollen of *T.*55, *I.C.*1472, a concentration of 0·015 per cent boric acid with 12·5 per cent sucrose gives the best results (78 per cent germination and 3,216μ long pollen tubes). Higher concentrations prove toxic, and 0·02 per cent boric acid brings down the germination to less than 5 per cent and the tube-length to 702μ. Similarly, in the variety *T.*25, a concentration of 0·015 per cent boric acid with 25 per cent sucrose gives 53 per cent germination and 3,636-μ long tubes. Here satisfactory germination occurs with even 0·02 per cent boric acid, but concentrations higher than this cause a marked inhibition of germination as well as tube growth.

The pollen tubes grow very rapidly, show a high rate of protoplasmic streaming and attain a length of about 4,000μ or more during 2–4 hr. growth *in vitro*. Callose plugs develop frequently in the tubes, and in abnormal cases branching tubes were also recorded. Swelling of the pollen-tube tips and other morphological abnormalities are observed at higher temperatures and in supra-optimal concentrations of sucrose and boric acid.

To the best of my knowledge, this is the first report of a successful germination of the pollen of Gramineae *in vitro*. The length of pollen tube obtained here (4,320μ) is similar to that required to affect fertilization in Nature. The present work once again proves the vital and useful part played by boron in pollen germination and pollen tube growth.

I am grateful to Prof. P. Maheshwari and Dr. B. M. Johri for advice and encouragement.

Toxicity of Gibberellin to Seedless and Seeded Varieties of *Vitis vinifera*

Experiments in 1957 at the University of California showed that gibberellic acid (hereinafter referred to as gibberellin) affected set of fruit, berry size, elongation of cluster parts, fruit composition, and vegetative growth of grapes[1,2]. In the spring of 1958 delayed foliation and dead buds were noted on certain seeded varieties that had received high concentrations in 1957. Observations were therefore continued for two more seasons to determine the damage and to see whether production would return to normal.

The five seeded varieties, being similar in response, are represented here by Red Malaga, various vines of which were sprayed in 1957 with gibberellin at one of three stages (pre-bloom, full-bloom, and after berry shatter). Shoots and clusters were counted in April of 1958 and 1959, and crop weights were measured in September or October. Since the results were essentially alike, regardless of spray date, only the full-bloom spraying is represented here (Table 1). Gibberellin applied in 1957 decreased the shoot and cluster count in 1958 on vines that received 25 p.p.m., and significantly decreased crop weight on vines that received 5 or 25 p.p.m. By 1959, however, recovery was complete. A good yield in 1959 on vines that received 25 p.p.m. in 1957 was probably a result of the low crop in 1958. Thus, injured vines had recovered within two seasons.

The seedless varieties used were Thompson Seedless (Sultanina) and Black Corinth. On June 10, 1957

Table 1. Response of Red Malaga Grapes to Various Concentrations of Gibberellin Sprays applied on June 4, 1957

Concentration of gibberellin (p.p m.)	Shoot count (No. per vine) 1958	Shoot count (No. per vine) 1959	Cluster count (No. per vine) 1958	Cluster count (No. per vine) 1959	Crop weight (lb. per vine) 1958	Crop weight (lb. per vine) 1959
0	26·8	22·0	19	13	30·2	16·3
0·1	24·2	27·0	19	16	27·9	18·9
1	22·8	24·0	17	12	24·9	12·8
5	20·3	21·0	16	8	12·4	11·8
25	2·0	24·0	0	18	3·6	24·0
d 0·05	5·3	N.S.	3·9	N.S.	8·5	4·0

(after berry shatter), Thompson Seedless vines, four per treatment, were sprayed with gibberellin at 0, 5, 20, or 50 p.p.m. The same vines were similarly sprayed in 1958 and 1959 at the same physiological stage of development. Table 2 shows the harvest results for 1957 and 1959. Gibberellin at 20 and 50 p.p.m. produced greatly enlarged berries in 1958 but had much less effect in 1959, probably because the crop was unusually heavy. The percentage of total soluble solids (degrees Balling) in 1959 was typical of other years. This experiment shows that gibberellin is non-toxic to Thompson Seedless grapes.

Table 2. RESPONSE OF THOMPSON SEEDLESS GRAPES TO VARIOUS CONCENTRATIONS OF GIBBERELLIN SPRAYS APPLIED IN JUNE 1957

Concentration of gibberellin (p.p.m.)	Average weight fruit per vine (lb.) 1959	Average weight per berry (gm.) 1957	1959	Degrees Balling 1957	1959
0	19·5	1·59	2·30	22·4	22·2
5	32·1	1·91	2·62	23·2	22·6
20	37·1	2·71	2·89	18·9	21·4
50	44·3	3·15	2·59	17·6	17·3
d 0·05		0·13		0·7	

One Thompson Seedless and one Black Corinth vine, sprayed after flowering in two consecutive years, showed no visible injury from 1,000 p.p.m. and 100 p.p.m., respectively. Thus, high concentrations are non-toxic to the seedless varieties although far lower concentrations are highly toxic to the seeded varieties studied. A generalization must await tests with more varieties.

The difference between seeded and seedless grapes in sensitivity to gibberellin probably relates to differences previously noted[3,4]. Girdling shortly after flowering greatly enlarges seedless grapes but has little effect on seeded varieties[3]. Thinning, in contrast, ordinarily increases berry size in seeded grapes but not much in seedless grapes[4]. Gibberellin increases size of seedless fruit, but has little or no effect on seeded grapes. It is interesting, therefore, that natural gibberellins have been found in seedless, but not in seeded, varieties[5].

This work was supported in part by grants from Merck and Co., Inc., Rahway, New Jersey, and from Abbott Laboratories, North Chicago, Illinois.

ENTOMOLOGY

Breeding of the Rabbit Flea, *Spilopsyllus cuniculi* (Dale): Requirement of a 'Factor' from a Pregnant Rabbit for Ovarian Maturation

A STUDY of the biology of the European rabbit-flea (*Spilopsyllus cuniculi*) was commenced by this department when it became apparent that it was an important vector of myxomatosis in Great Britain. A technique for the laboratory culture of the flea was required, but was not rapidly forthcoming. It was repeatedly found that fleas released on domestic or wild rabbits kept in various types of hutches failed to produce eggs. However, Miriam Rothschild[1] reported that the flea bred when rabbits were kept under semi-natural conditions in an outdoor enclosure, and with her encouragement a study was made of ovarian development in the flea (Mead-Briggs, A. R., unpublished work).

Recently we found that if the fleas were placed on pregnant does the ovaries of the fleas matured and eggs were laid in the nest shortly after the young were born, whereas the ovaries of fleas kept on non-pregnant rabbits did not develop. In one experiment to follow the maturation of the ovaries up to ovulation, thirty-five female and twenty-five male virgin fleas were released on each of four rabbits housed in similar two-compartment hutches, one compartment being dark for nesting. The rabbits were: (1) a non-pregnant adult doe; (2) a doe pregnant 1–2 days; (3) a doe pregnant 11 days; (4) a doe pregnant 20 days. Samples of three female fleas were removed periodically (after a minimum of 10 days on the rabbits), and the reproductive systems dissected out. The degree of development of the ovaries was assessed by measurement of the length of the proximal oocyte follicle in one of the ovarioles. (In one individual there is little variation in this dimension between the several ovarioles until shortly before ovulation; then the final stage of egg maturation and subsequent ovulation occurs in only half the ovarioles at a time (Mead-Briggs, A. R., unpublished work).)

The results for fleas from rabbits 1 and 2 are shown in Fig. 1, each point being a mean obtained from the measurement of three dissected specimens. The absence of change in size (from that of immaturity) of the first oocyte follicle of the fleas kept for up to 28 days on the non-pregnant rabbit is contrasted with the increase occurring among fleas fed on the pregnant rabbit.

The rate and period of growth of the ovaries of the fleas fed on the three pregnant rabbits is indicated in Fig. 2. Maximum development is reached at the time of parturition when the fleas immediately leave the adult and are to be found only in the nest or on the nestlings. Development of the ovaries appears to commence about 10 days prior to parturition although the size of the eggs produced may be influenced by

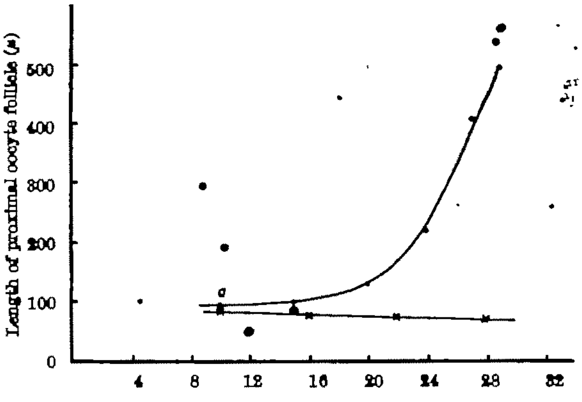

Fig. 1. Development of proximal oocyte follicle of fleas fed on pregnant and non-pregnant rabbits. Point *a* corresponds to the eleventh day of pregnancy. ●, Fleas from rabbit 2; ×, fleas from rabbit 1

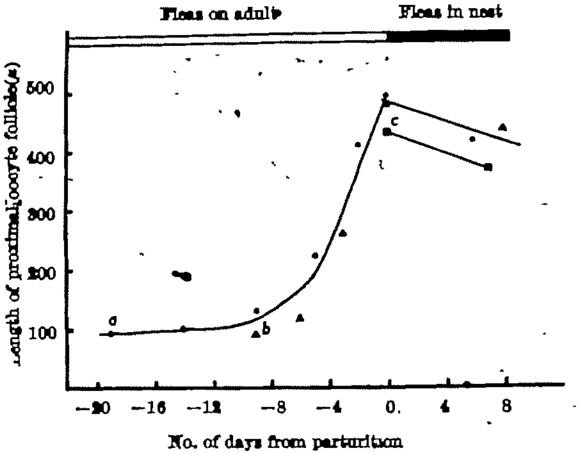

Fig. 2. Development of proximal oocyte follicle of flea related to time of parturition by host. Points *a*, *b* and *c* correspond to stage of development after 10 days feeding on respective rabbit. ●, Fleas from rabbit 2; ▲, fleas from rabbit 3; ■, fleas from rabbit 4

the feeding life of the flea. Thus fleas from rabbit 4 which could only feed for 10 days before commencing egg laying had relatively small eggs (although they were fully fertile) compared with fleas that fed for 19 and 29 days (rabbits 3 and 2 respectively).

At present the nature of the factor initiating ovarian development of the fleas fed on pregnant does is uncertain. Various controls have precluded it being related to nest-building habits by the pregnant rabbits. A likely hypothesis is that it is a factor, perhaps nutritional, present only in the blood of a pregnant rabbit and perhaps only at the required level during the later stages of pregnancy. Buxton[2] compared the production of eggs by *Xenopsylla cheopis* when fed on baby and adult mice and found that with the baby mice eggs were produced in smaller numbers and only after an unusual delay. He suggested this might result from the lack of mammalian sex hormones normally obtained in the blood of adult mice.

Wigglesworth[3] has shown that in a number of blood-sucking arthropods a small amount of hæmoglobin is absorbed into the hæmolymph without digestion, and some of this hæmoglobin is transferred with little change to the yolk of the developing eggs. He concluded that some of the normal protein constituents of egg yolk may perhaps be formed elsewhere in the insect body and merely transmitted to the yolk via the follicle cells and not synthesized in them. This could be the case in fleas which have simple, panoistic ovarioles lacking any trophic tissue other than the follicle epithelium. While flea eggs do not contain any pigmented hæmoglobin derivatives, variation in the serum proteins of the host could be important. Hence, in the present case, it may be significant that Brambell *et al.*[4] found marked differences between the sera of non-pregnant, adult rabbits and rabbits 25 days pregnant, both in respect of the total protein concentration and, in the proportions of the components.

So far as we are aware *Spilopsyllus cuniculi* is the only flea shown to require a pregnant host for egg maturation, but failures to breed a few species of flea in captivity may indicate others have similar requirements. The most important result of this mechanism which produces perfect synchronization between maturation of eggs by the flea parasite and parturition by the host is that the eggs are immediately ready to be laid in a microclimate ideal for further development provided by the rabbits' breeding nest.

Experimental Breeding of *Anopheles gambiae* Giles in Papyrus Swamps

In Uganda, *Anopheles gambiae* Giles does not breed in the interior of papyrus swamps, in their natural, undisturbed state. But a considerable amount of breeding may occur at the periphery, outside the papyrus zone, particularly in hoof-prints, cattle-drinking places, and open natural pools[1]. Also, where papyrus swamps have been drained and the land used for cultivating such crops as *Colocasia*, larvæ may be found in the shallow, sunlit pools between cultivation-mounds. On the whole, the swamps are not a potent source of malaria[2].

The composition and nature of the breeding water have a twofold influence on the mosquito, affecting not only the larvæ present in the water, but also the gravid adult female looking for a place to deposit its eggs[3]. However, although it seems quite clear that the ecological distribution of larvæ in Nature is largely a result of the different oviposition habits of the adult mosquito[4], it is also generally accepted that the absence of mosquito larvæ from a particular breeding place admits of two alternative interpretations: either (*a*) the females do not oviposit there at all; or (*b*) they do rather indiscriminately and that larvæ will develop in certain types of water and not in others. The preliminary observations reported in this communication were made to investigate alternative (*b*), that is, whether the absence of *A. gambiae* larvæ from the interior of papyrus swamps, in Uganda, is because they cannot develop in such habitats.

The observations were made in two papyrus swamps near Kampala. Cages made of nylon gauze or from iron drums were planted in the swamps. All predators were removed or prevented from entering the cages. This made the breeding conditions less natural; but it excludes the factor of predators from consideration of the results. Larvæ of *A. gambiae*, in various stages of development, were then placed in swamp water, in the cages, and all adults emerging afterwards were recorded and removed. The results of seven experiments are summarized in Table 1. Experiments 1 and 3 were made at the periphery of the swamp, just outside the papyrus zone; 5, just inside the papyrus zone; 4, 6 and 11, inside the swamp among tall papyrus and under considerable shade; and 10, inside the swamp, but in an exposed previously cut papyrus area.

Table 1 shows that 93·7 per cent of the 1,120 *A. gambiae* larvæ introduced into the papyrus swamps

Table 1. RECOVERY OF ADULT *Anopheles gambiae* GILES FROM LARVAE PLACED IN PAPYRUS SWAMPS

Exp. No.	No. and stage (in brackets) of larvae	Days since larvae were placed in swamp		Total of adults emerged	
		First adult emergence	Last adult emergence	No.	Percentage

3	100 (I)	26	28	3	3·0
4	140 (I, II, III, IV)	4		1	0·7
5	140 (I, II, III, IV)	3	23	7	5·0
6	200 (I, II, III, IV)	8	8	12	6·0
10	200 (IV)	3	9	10	5·0
11	200 (IV)	5	8	7	3·5

Totals: Larvae, 1,120; adults emerged, 70, that is, 6·3 per cent.
(N.B. In column 2, the numbers are totals of all the respective stages shown.)

did not complete their development to the adult stage. The detailed records indicate a very high mortality among the early stages. Generally, it would thus seem that the interior of papyrus swamps is extremely unfavourable for the development of *A. gambiae* larvae. Also, the duration of the larva–adult period appeared to be considerably longer than one usually finds in the favoured natural breeding places.

The water in papyrus swamps is characterized by a very high degree of organic pollution and by extreme deoxygenation[5,6]. It has been suggested that suitable larval food is absent from swamp waters[7] and that the middle of the swamp does not provide breeding facilities for *A. gambiae*, owing to the high degree of organic pollution of the water which obtains there[1]. Several authors have directed attention to the absence of larvae from water with large organic content[8]; although Harvey and Symes[9] report to the contrary. It is also known that *A. gambiae* may tolerate a considerable degree of animal pollution, but it is very sensitive to organic pollution of vegetable origin[3]. Pollution in papyrus swamps is caused by decaying vegetation, and *A. gambiae* would thus be very sensitive to it. The view that an increase in the proportion of organic matter in natural breeding-places slows down the development of *A. gambiae* larvae[10] is supported by the present observations. But, how far the predominantly anaerobic conditions of the swamp waters affected the results of our observations is not very clear. Since the larvae depend on atmospheric air and are not forcibly prevented from periodically rising to the surface to breathe, lack of oxygen in the medium is not a respiratory problem. But it can influence the length of time during which the larvae are submerged and this seems to be ecologically important.

Taxonomic Significance of Spermathecal Structure in Some Species of *Tribolium*

RECENT examination of spermathecae in tenebrionid beetles associated with stored products has revealed that there are two distinct types of structure which are termed here the 'tenebrio' type and the 'chamber' type. Their basic plan and relationship to the rest of the female reproductive system are similar; but there are certain differences which, in regard to the genus *Tribolium*, are considered to be of some phylogenetic significance. In both types a duct of varying width and length, which terminates in the main sperm storage region, arises from the common oviduct. In *Tenebrio molitor* this duct is short and wide and ends in a group of convoluted, thin-walled tubes bound together by a tough membrane. Arising from their common base is a single, longer structure which may be glandular, having large-celled walls and a restricted lumen. Dissection of fertilized females has shown that the convoluted tubes carry sperm. In the chamber type, found in *Gnathocerus*, *Alphitobius*, *Alphitophagus* and some *Tribolium* species, there is a similar duct which runs to a strongly chitinized chamber in which motile spermatozoa are easily detected. This is variously shaped and arising either from the end opposite the duct entrance or from the side is a more-or-less elongate glandular region. In *Palorus* species this basic pattern is modified, associated with a muscular bursa.

The genus *Tribolium* has been divided on external morphological features into five species groups, namely, *brevicornis*, *confusum*, *alcine*, *castaneum* and *myrmecophilum*, associated with the following geographical regions, America, Africa, Madagascar, Indo-Australia and the Malay peninsula and East Indies respectively[1]. The spermathecae of five species from the *castaneum* and *confusum* groups have recently been examined in some detail, and it was found that the structure in *T. castaneum* and *madens* (*castaneum* group) closely resembled that of *Tenebrio* whereas *T. confusum*, *anaphe* and *destructor* (*confusum* group) had the more common chamber type of spermatheca. In the former species the duct was very short, terminating in a number of long, convoluted tubes invested in a tough, elastic membrane. These tubes were found to contain spermatozoa. Connected to the common base of the tubes by a chitinized collar was a short, glandular region. In the latter species the duct was again short and wide, but terminated in a junction, one arm of which entered a strongly chitinized S-shaped chamber, while the other arm ran into a glandular region which was long in *anaphe* and *destructor* but shorter in *confusum*.

The present evidence supports the maintenance of the *confusum* (African) and *castaneum* (Indo-Australian) groups while further work is required to indicate similar associations between the other species groups mentioned here. Also, with regard to the suggestion that *T. molitor* and *obscurus* originated in Europe or Asia and were only later transported to Africa and America[2], possible affinities between the *castaneum* group and *tenebrio* species, and the evolutionary significance of the structures described here, must be considered.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, September 26

Oliver Bird Trust; British Society for Immunology; and the Society for the Study of Fertility (in the Large Lecture Theatre, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5 p.m.—Dr. Albert Tyler (California Institute of Technology): "Immunological Approaches to Fertility Control" (Fourth Oliver Bird Lecture).*

Society of Chemical Industry, Pesticides Group (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Dr. H. H. Colhoun: "Interpretations of Insecticidal Action".

Tuesday, September 27—Thursday, September 29

Department of Scientific and Industrial Research (at the Connaught Rooms, Great Queen Street, London, W.C.2), at 10 a.m. daily—Conference on "Ergonomics in Industry".

Wednesday, September 28

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Discussion on "The Land Colour Theory with Particular Reference to its Applications to Colour Television".

Oil and Colour Chemists' Association (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 7 p.m.—Mr. W. F. Jenkins, Mr. A. Mott and Dr. R. J. Wicker: "Unsaturated Polyesters for Surface Coatings".

Society for Psychical Research (in the Court Room, Caxton Hall, London, S.W.1), at 7 p.m.—Dr. W. Grey Walter: "Neurophysiological Aspects of Hallucinations and Illusory Experiences" (Myers Memorial Lecture)*.

Thursday, September 29—Friday, September 30

Worshipful Society of Apothecaries of London, Faculty of the History of Medicine and Pharmacy (at Apothecaries Hall, Black Friars Lane, London, E.C.4 (mornings), the Royal Society of Medicine, 1 Wimpole Street, London, W.1, on Thursday afternoon, and at the Royal College of Physicians, Pall Mall East, London, S.W.1, on Friday afternoon)—First British Congress on the History of Medicine and Pharmacy.

Society of Chemical Industry, Surface Activity Group (at the Royal Institution, 21 Albemarle Street, London, W.1)—Symposium on "Powders in Industry—Properties and Principles of Application".

Saturday, October 1

Association of Clinical Biochemists (joint meeting with the Association of Clinical Pathologists, at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 9.30 a.m.—Annual General Meeting and Symposium on "Malabsorption".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Senior Technical Assistant (with experience in the use of transistors, and preferably familiar with nuclear instrumentation) in the Physics Department, to help in the design and construction of electronic and other instruments to be used in artificial Earth satellites—The Secretary and Registrar, The University, Southampton (September 28).

Assistant Lecturer, Grade B (with a good honours degree) in the Department of Pure and Applied Physics, to teach up to degree level—The Registrar, Royal Technical College, Salford 5, Lancs (September 30).

Plant Physiologist (with a good honours degree in botany and research experience), for investigation of effects of temperature, oxygen and carbon dioxide on the respiration of apples—The Director, Ditton Laboratory, Agricultural Research Council, Larkfield, Maidstone, Kent (September 30).

Lecturer (with an honours degree, and preferably with a higher degree in chemistry with postgraduate experience of academic or industrial research) in Physical Chemistry—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3 (October 1).

Lecturer (with special qualifications or interests in cytogenetics or experimental taxonomy) in Botany in St. Salvator's College—The Joint Clerk to the University Court, College Gate, St. Andrews (October 1).

Assistant Lecturer (preferably with a degree or National Diploma in Horticulture and an interest in forestry, and sound experience in practical work and, if possible, in teaching) in Horticulture at the Cumberland and Westmorland Farm School, Newton Rigg, near Penrith, and for lecturing, demonstration and advisory work in the two counties—The Director of Education, 5 Portland Square, Carlisle (October 3).

Lecturer or Assistant Lecturer in Pharmacy in the Department of Pharmacology, The Registrar, The University, Leeds (October 3).

Lecturer (preferably medically qualified) in the Department of Physiology—The Secretary, The University, Aberdeen (October 3).

Senior Lecturer/Lecturer (with an appropriate honours degree or equivalent qualifications) in Polymer Science at the University of New South Wales, Australia—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2, and The Bursar, University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (October 3).

Computing Assistant (Administration) (preferably with an honours degree in mathematics or in a pure or applied science, and either a Diploma in Electronic Computing, or appropriate experience in data processing by electronic computer, or, preferably, both), to work jointly in the Electronic Computing Laboratory and in the office of the Registrar—The Registrar, The University, Leeds 2 (October 4).

Assistant Lecturer (with special qualifications in physical chemistry) in Chemistry—The Registrar, The University, Manchester 13 (October 15).

Laboratory Technician (holding either A.M.I.L.T. or the Advanced City and Guilds of London Institute Certificate for Laboratory Technicians or equivalent qualification) at the Technical College, Bulawayo, Federation of Rhodesia and Nyasaland, for demonstration assistance to the Lecturing staff in the laboratories and maintenance and preparation of equipment—The Secretary (*R*), Rhodesia House, 429 Strand, London, W.C.2 (October 15).

Lecturer in Organic Chemistry in the Department of Chemistry and Chemical Engineering, University of Natal, Durban, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, October 15).

Lecturer or Assistant Lecturer (with a registrable medical qualification) in Anatomy at the University College of the West Indies—The Secretary, Senate Committee on Colleges Overseas in Special Relation, University of London, Senate House, London, W.C.1 (October 15).

Senior Lecturer and a Lecturer (with a degree in science or in agriculture, followed by postgraduate training in biochemistry, and previous experience in teaching or research) in Biochemistry at Canterbury Agricultural College, University of New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, October 15).

Demonstrators in Biochemistry, Botany and Physics at the University of Adelaide—The Registrar, University of Adelaide, Adelaide, South Australia (October 20).

Assistant Lecturer or Lecturer in the Department of Veterinary Pathology—The Registrar, The University, Liverpool (October 31).

Chair of Anatomy, and Chair of Physiology in Monash University, Clayton, Victoria, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, October 31).

Lecturer in Chemistry at the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, October 31).

Lecturer/Senior Lecturer in Zoology at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, October 31).

Senior Lecturer or Lecturer in Physics at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, October 31).

Lecturer in Education at Victoria University of Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, November 1).

University Lecturer (with at least an honours degree in psychology and some knowledge of statistical methods) in Psychology—The Secretary, Cambridge University Department of Education, 17 Brookside, Cambridge (November 3).

Chair of Philosophy—The Registrar, The University, Hull (November 30).

Research Fellow (Organic Chemist) in the Department of Medical Chemistry, John Curtin School of Medical Research, Australian National University, to work with Prof. A. Albert or Dr. D. J. Brown on problems in the pyrimidines, pteridines or other hetero-aromatic series, and take up duties in Canberra in 1961—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, November 30).

Biochemist (with an appropriate science degree or the A.R.I.C.) within the Nottingham No. 2 Group of Hospitals, to work under the direction of the Chemical Pathologist at the City Hospital, where there is a fully equipped biochemical laboratory—J. H. Hargreaves, Group Secretary, Nottingham No. 2 Hospital Management Committee, Sherwood Hospital, Hucknall Road, Nottingham.

Director of Research (with the highest administrative and negotiating ability, academic qualifications and technical experience) of the Machine Tool Industry Research Association—The Chairman of Council, Machine Tool Industry Research Association, Brettenham House, Lancaster Place, London, W.C.2, marking envelope "R.A. Application".

International Wool Secretariat Research Fellow (with a degree in physics or physical chemistry with some research experience, and able to undertake work on the structure of protein fibres generally and wool in particular), to work in conjunction with Dr. F. Happey, Head of the Department of Textile Industries—The Clerk to the Governors, Bradford Institute of Technology, Bradford.

Lecturer (with good academic qualifications in chemistry, together with industrial and/or research experience) in Surface Coatings; and an Assistant Lecturer, Grade B (with good academic qualifications, and preferably some teaching or industrial experience) in Organic Chemistry in the Department of Chemistry and Food Technology—Clerk to the Governing Body, Borough Polytechnic, Borough Road, London, S.E.1.

LECTURER (with qualifications in mineralogy and petrology and an active interest in Pre-Cambrian rocks and ore deposits) IN GEOLOGY at the University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

MEDICAL RESEARCH OFFICER (with registrable medical qualifications and aptitude for research, and preferably postgraduate research experience in the epidemiology of insect-borne diseases) WITH THE EAST AFRICAN TRYPANOSOMIASIS ORGANIZATION, to undertake research on the epidemiology of human trypanosomiasis—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.195/198/02.

PATENT EXAMINERS and PATENT OFFICERS (age at least 21 and under 29 (30 for Examiners), with a first- or second-class honours degree in physics, chemistry, engineering or mathematics, or equivalent attainment, or professional qualification, for example, A.M.I.C.E., A.M.I.Mech.E., A.M.I.E.E., or A.R.I.C.), for work on the examination of patent applications—Civil Service Commission, 17 North Audley Street, London, W.1, quoting S/128/60, and stating date of birth.

RESEARCH ASSISTANT (with a degree in chemistry, G.R.I.C. or Dip. Tech.) IN CHEMISTRY, for fundamental work on the measurement of pH values—The Head of the Department of Applied Chemistry, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

RESEARCH ASSISTANT (with graduate or equivalent qualifications and appropriate experience in electronic instrument design and construction) IN THE DEPARTMENT OF PHYSICS, to take part in a space research project under Dr. T. R. Kaiser. The work will involve the development of instruments for installation in rockets and satellites—The Registrar, The University, Sheffield.

RESEARCH FELLOW (Ph.D. standard in chemistry or physics and a sound knowledge of electronics), and a RESEARCH STUDENT, for research on new developments of nuclear magnetic resonance spectroscopy—The Secretary, Department of Chemistry, King's College, Strand, London, W.C.2.

SCIENTIFIC OFFICER (honours graduate in chemistry or biochemistry) IN THE RADIOBIOCHEMISTRY DEPARTMENT, for biochemical research involving the use of radioactive isotopes, and in particular C^{14} and tritium—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting Ref. 60/T.

SENIOR LECTURER (with specialist knowledge of crop husbandry) IN AGRICULTURE—The Clerk to the Governors, Essex Institute of Agriculture, Writtle, near Chelmsford, Essex.

SENIOR TECHNICIAN I IN THE DEPARTMENT OF EXPERIMENTAL PATHOLOGY, to assist in the research programme (no routine work involved)—The House Governor, St. Mary's Hospital, Paddington, London, W.2.

SENIOR TECHNICIAN or TECHNICIAN (with experience and training in electronics) IN THE PHARMACOLOGY DEPARTMENT—The Secretary, Royal Free Hospital School of Medicine, Hunter Street, London, W.C.1.

TEMPORARY RESEARCH ASSISTANT (with a first- or second-class honours degree in zoology or botany) IN THE PLANT PATHOLOGY LABORATORY, Ministry of Agriculture, Fisheries and Food, Harpenden, for work on biology and control of Stem and Bulb Eelworm in Narcissus bulbs—The Ministry of Labour, Technical and Scientific Register, Almack House, 26 King Street, London, S.W.1, quoting G.245/0A.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

Colonial Office. The Colonial Territories, 1959–1960. Pp. vi+147. (Cmnd. 1065). (London: H.M. Stationery Office, 1960.) 6s. 6d. net. [57

Committee of Vice-Chancellors and Principals of the Universities of the United Kingdom. Second Report of an *ad hoc* Committee on Procedure for Admission of Students. Pp. vi+31. (London: Committee of Vice-Chancellors and Principals of the Universities of the United Kingdom, 1960.) 2s. [57

Department of Scientific and Industrial Research: Laboratory of the Government Chemist. Report of the Government Chemist from 1st April, 1958 to 31st December, 1959. Pp. iv+56. (London: H.M. Stationery Office, 1960.) 2s. 6d. net. [57

Ministry of Education. 15 to 18: Report of the Central Advisory Council for Education—England. Part 2: Surveys. Pp. xviii+240. (London: H.M. Stationery Office, 1960.) 8s. 6d. net. [57

The Place of Physiology in University Education. By Prof. J. A. B. Gray. (An Inaugural Lecture delivered at University College, London, 23 February, 1960.) Pp. 16. (London: H. K. Lewis and Co., Ltd., 1960.) 2s. 6d. net. [57

Department of Scientific and Industrial Research: National Physical Laboratory. Mathematical Tables, Vol. 3: Tables of Generalized Exponential Integrals. By G. F. Miller. Pp. iii+43. (London: H.M. Stationery Office, 1960.) 7s. 6d. net. [57

Government Publications. Sectional List No. 1: Agriculture and Food—Publications prepared by the Ministry of Agriculture, Fisheries and Food. Pp. 36. (London: H.M. Stationery Office, 1960.) [67

Library Association. Library Telex Directory: a List of Libraries in the United Kingdom with access to Telex. Pp. ii+15. (London: Library Association, Reference, Special and Information Section, 1960.) [67

Department of Scientific and Industrial Research. Scientific Research in British Universities, 1959–60. Pp. xii+492. (London: H.M. Stationery Office, 1960.) 25s. net. [87

Russian Review of Biology, Vol. 48, No. 1 (July-August, 1959). Pp. 1–110. Translated from the Russian. Subscription rates: £9 or 30 dollars for the first nine issues (Vol. 48, Parts 1, 2 and 3 of 1959, and six issues of 1960.) Thereafter annual subscription will be £6 10s. or 20 dollars. Single issues 30s. or 5 dollars. Published six times a year. (Edinburgh and London: Oliver and Boyd, Ltd., 1959.) [87

Other Countries

European Organization for Nuclear Research, CERN. Annual Report, 1959. Pp. 102 (25 plates). Inauguration of the Proton Synchrotron, 5 February 1960. Pp. 22 (8 plates). (Geneva: CERN, European Organization for Nuclear Research, 1960.) [57

New Zealand Forest Service: Forest Research Institute. Research Notes. No. 13: Relations between Vertebrates and Forest after the 1955 Fire at Balmoral State Forest. By Thane Riney and C. L. Batcheler. Pp. 15. No. 19: Combined Taper and Volume Tables for *Pinus radiata*, New Zealand, 1957; Shelterbelts; and for *Pseudotsuga taxifolia*, New Zealand, 1958: All Stands. By S. W. Burstall. Pp. 63. (Wellington: Government Printer, 1959.) [57

Zoology Publications from Victoria University of Wellington, New Zealand. No. 26: Synoptic Keys to the Genera of Ophiuroidea. By H. Barraclough Fell. Pp. 44. (Wellington, New Zealand: Victoria University of Wellington, 1960.) [57

Association of Food Technologists, Mysore. Annual Review of Food Technology, Vol. 1, 1959. Pp. 155. (Mysore: Association of Food Technologists, Central Food Technological Research Institute, 1960.) Rs. 5; 10s. [57

On Quantum Mechanics in Acceleration Field. By Nagatoshi Tunasima. Pp. v+39. (Tokyo: The Sanshusha Press, 1960.) [57

Comptes Rendus des Travaux du Laboratoire Carlsberg. Vol. 31, No. 25: On the Kinetics of Protein Isomerization Processes: Mechanisms Providing for Rapid Approach to an Equilibrium between Slowly Interconverting Species. By Joseph F. Foster. Pp. 351–371. 3 kr. 85 øre. Vol. 31, No. 26: The *in vitro* Uptake of Fluorescein Labelled Plasma Proteins. 1. Mature Cells. By H. Holtzer and S. Holtzer. Pp. 373–408+8 plates. 4 kr. 50 øre. Vol. 31, No. 27: Observations on Yeast Protoplasts. By H. Holtzer and Paul Ottolenghi. Pp. 409–422+8 plates. 2 kr. 25 øre. (Copenhague: Danish Science Press, Ltd., 1960.) [57

Commonwealth Scientific and Industrial Research Organization, Australia. List of Publications. Pp. 46. (Melbourne: Commonwealth Scientific and Industrial Research Organization, 1960.) [57

Research Council of Alberta. Fortieth Annual Report, 1959. Pp. v+54. (Report No. 79). (Edmonton: Research Council of Alberta, 1960.) [57

Bulletin of the Madras Government Museum. New Series, General Section, Vol. 7, No. 5: The Gopuras of Tiruvannamalai. By F. H. Gravely. Pp. iii+8+13 plates. 5 rupees 90 naye Paise. Handbook of Museum Technique. Edited by Dr. A. Aiyappan and Dr. S. T. Satyamurti. Pp. xvii+228 (11 plates). 2 rupees 75 naye Paise. (Madras: Madras Government Museum, 1959 and 1960.) [57

Polish Academy of Sciences: Distribution Centre for Scientific Publications. Quarterly Review of Scientific Publications, Series A—Social Sciences, No. 1 (9), 1960. Pp. 41. (Warsaw: Polish Academy of Sciences, 1960.) [67

Regional Research Centre of the British Caribbean at the Imperial College of Tropical Agriculture, Trinidad, W.I. Soil and Land-Use Surveys No. 9: Grenada. By K. C. Vernon Hugh Payne, and J. Spector. Pp. 42 (2 plates). (St. Augustine, Trinidad: Imperial College of Tropical Agriculture, 1960.) 18s. [87

The Quantum Hypothesis: a Criticism and Emendation. By Prof. B. M. Sen. Pp. 13. (Calcutta: The University Press, 1960.) [87

National Research Council of Canada: Associate Committee on Geodesy and Geophysics. *Canadian Geophysical Bulletin*, Vol. 12. Pp. v+95. (Ottawa: National Research Council of Canada, 1959.) [87

Archives de l'Institut de Paléontologie Humaine. (Fondation Albert 1er, Prince de Monaco). Mémoire No. 30: La Grotte de Rochereil: Station Magdalénienne et Azilienne. Par Dr. P. E. Jude. Pp. 74. (Paris: Masson et Cie., 1960.) [87

Institut des Parcs Nationaux du Congo Belge. Exploration du Parc National Albert. Mission F. Bourlière et J. Verschuren. Fascicule 1: Introduction a l'Ecologie des Ongulés du Parc National Albert. Par Francois Bourlière et Jacques Verschuren. Pp. 158+planches 1–49. Exploration du Parc National Albert. Mission J. Lebrun (1937–1938). Fascicule 2: Etudes sur la Flore et la Végétation des Champs de Lave au Nord du Lac Kivu (Congo Belge). Par Jean Lebrun. Pp. 352+planches 1–13. (Bruxelles: Institut des Parcs Nationaux du Congo Belge, 1960.) [87

Program for Scientific Translations, Jerusalem. Soviet Science in English—Catalogue. Pp. 24. (Jerusalem: Program for Scientific Translations, 1960.) [87

Laboratoire d'Astronomie de Lille. Astronomical Newsletter, No. 100. Pp. ii+53. (Lille: Laboratoire d'Astronomie, 1960.) [87

National Science Foundation, Washington, D.C. Weather Modification: First Annual Report for Fiscal Year ended June 30, 1959. Pp. iii+16. (Washington, D.C.: Government Printing Office, 1960.) 35 cents. [117
